MANUAL

OF

CHEMISTRY:

BY

WILLIAM THOMAS BRANDE,
OF HER MAJESTY'S MINT;

FELLOW OF THE ROYAL SOCIETIES OF LONDON AND EDINBURGH; FELLOW OF THE UNIVERSITY
OF LONDON; PROFESSOR OF CHEMISTRY IN THE ROYAL INSTITUTION; PROFESSOR OF
CHEMISTRY AND MATERIA MEDICA TO THE APOTHECARIES' COMPANY; HONORARY
MEMBER OF THE IMPERIAL SOCIETY OF NATURALISTS OF MOSCOW; OF
THE IMPERIAL PHARMACEUTICAL SOCIETY OF ST. PETERSBURGH;
OF THE PHYSICO-MEDICAL SOCIETY OF ERLANGEN; OF THE
LITERARY AND PHILOSOPHICAL SOCIETY OF NEW YORK;
OF THE FRANKLIN MECHANICAL INSTITUTE
OF PENNSYLVANIA, &c., &c., &c.

FIFTH EDITION, GREATLY ENLARGED.

TO
CHARLES HATCHETT, Esq.,

F.R.S. L. & E., F.A.S.,

CORRESPONDING MEMBER OF THE ROYAL ACADEMY OF SCIENCES OF PARIS,

&c. &c. &c.

MY DEAR SIR,

To you, as my first Instructor in Chemistry, and as one whose Researches in the Science have raised your Name to a high Station among British Chemists, I beg leave to dedicate the following Work; trusting that you will receive it as a Testimony of the Gratitude and Respect with which I shall always remain,

Faithfully and affectionately yours,

WILLIAM THOMAS BRANDE.

ROYAL MINT,
1st May, 1841.

PREFACE.

THIS Work was originally intended as a text-book, for the use of the Chemical Students in the Royal Institution, but the reception of the first edition by the Public, its translation into French, German, and Italian, and its re-publication in America, induced me to improve and enlarge it, and to endeavour to render it more worthy of such marks of approbation.

The present Edition differs materially from its predecessors in all respects, except the general arrangement of its contents; this I have retained as in the original, under the conviction that it answers the purposes of the student: I have, in fact, re-written a large portion of the present volume; for the progress of Chemical Philosophy since the first appearance of this Work has been such, as to give a new character to some of its leading departments, and more or less to influence the theoretical as well as the practical details of almost all its branches. To this progress, the researches of my friend and colleague Professor Faraday have pre-eminently contributed: his discoveries in Electricity have so modified and extended the chemical bearings of that extraordinary power of matter, as to vie in importance with those of his great predecessor in the same school; while the skill with which he has traced out their connexion with physical phenomena, has gone far to withdraw some of the barriers between Chemical and Physical Science.

Organic Chemistry has also of late years assumed a new and striking aspect: the Atomic Theory has proved a powerful engine in removing many of the difficulties which encumbered its study; and the skilful activity with which its experimental details have been pursued by some of the ablest Chemists of Germany and France, has not only already been rewarded with a full measure of

interesting discovery, but has opened new and extended views to future inquirers.

These have been the principal sources of the recent changes in the aspect of Chemical Science; and whilst they have greatly contributed to its existing interest and importance, they present a promising picture of its future resources.

I have endeavoured, in this volume, to place before the reader a faithful outline of the present state of Chemistry, adapted chiefly for the instruction of the beginner, and for the use of the Student in this delightful branch of experimental Science: writing therefore for the uninitiated, and for the learner, much has been sacrificed to perspicuity, and to simplicity of detail. I must at the same time observe, that Chemistry is not what it was; that with whatever intention the pupil enters upon its study, it will require labour and thought to become usefully acquainted even with its elementary details; and that to reap advantages from its applications either to the purposes of the multitudinous Arts which are dependent upon it, or to the extension of the Sciences which are leagued with it, will perhaps demand more time and study than he is aware of. I believe that the depths of Chemistry are, with the aids which it now enjoys, more easily fathomed than those of most other branches of Physical Science, and am certain that it is admirably calculated to awaken and to gratify curiosity in regard to the phenomena both of Nature and of Art; but it is not now, as formerly, the bare history "of the effects of heat and mixture;" those who enter seriously upon its study must be prepared for some intellectual exertion and mental labour: they will then find that its connexion with other Sciences, with the arts of life, and the phenomena of nature, is such, as to render it at once useful and popular, and an essential in the range of a liberal education.

But, though chiefly addressed to the Student, I am not without hope that this Manual will be approved by the practical and experimental Chemist, especially by the Teacher of the Science: to such I have endeavoured to recommend it by copious references to authorities, and by abstracts of practical directions. Should it in these respects prove a work of reference worthy of his occasional consultation, another object will be answered.

In consequence of the popular applications of Chemistry, and

its extensive connexion with the useful and ornamental Arts, and with the Sciences at large, the general reader finds it often forced upon him; its terms are of frequent occurrence, and its language is in daily use: I have, therefore, added to this Work a copious Index, intended in some measure to supersede the use of a Chemical Dictionary.

In conclusion, I have to observe that the note-books of my Lectures have served as a foundation of the present volume, and that these include a miscellaneous collection of original and borrowed information: although, therefore, I have endeavoured, as far as possible, to refer to authorities, and to cite the sources of my statements, I fear that I may often have unintentionally omitted such acknowledgments. The systematic and elementary works which I have principally consulted, are those of Dr. William Henry, Dr. Thomas Thomson, Dr. Edward Turner, Professor Daniell, and Professor Graham; and of Berzelius, Dumas, Gmelin, Mitscherlich, Thenard, and Liebig; and the Dictionaries of Messrs. Aikin and Dr. Ure; together with the Transactions of the Royal Society, and the English and Foreign Journals: among the latter, the *Annales de Chimie et Physique*, and Poggendorff's *Journal*, are especially rich in original Chemical information.

In the preliminary remarks to the chapter on Simple Substances, are explained the principles of the Notation and Symbols which I have found it convenient to adopt, and my reasons for deviating a little upon these points from the high and accepted authority of Berzelius.

It must be the anxious wish of all who are conversant with our Science, that an uniform system of Symbols, Notation, and Equivalent, should be agreed upon and adhered to, and it is to be hoped that the British and Foreign Scientific Associations will seriously direct their exertions towards the attainment of so important an object.

The general method which I have adopted of representing the Atomic, Equivalent, and Percentage, composition of bodies, is that employed by Leopold Gmelin in his excellent *Handbuch der Theoretischen Chemie*; it saves repetition, and brings much information before the eye of the Student in a clear but condensed form; I insert the following statement of the composition of Nitrous

Oxide as an explanatory specimen of one of these tables, in its most general and extended form.

I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.
	A.	E.	Pr. Cent.	Davy.	Berzelius.	Higgins.	Vols.	Sp. Gr.	100 C.I.
Nitrogen . .	1	14	63·6	63·3	62·5	60	1·0	0·97	30·1
Oxygen . .	1	8	36·4	36·7	37·5	40	0·5	0·55	17·05
Nitrous oxide	1	22	100·0	100·0	100·0	100	1·0	1·52	47·21

The first column (I.) contains the component parts of nitrous oxide; (II.) shows that 1 atom of nitrous oxide is composed of 1 atom of nitrogen and 1 of oxygen; (III.) shows the equivalent weight of an atom of nitrogen = 14 and an atom of oxygen = 8, producing an atom of nitrous oxide = 22; (IV.) shows the composition *per cent.* calculated from the theoretical equivalents; (V.) (VI.) and (VII.) show the experimental results of the analyses of Davy, Berzelius, and Higgins, and enable us to compare them with the calculated or theoretical composition; (VIII.) shows that 1 volume of nitrogen and half a volume of oxygen, constitute 1 volume of nitrous oxide; (IX.) shows that the specific gravity of nitrogen being 0·97 and half the specific gravity of oxygen being 0·55, the specific gravity of nitrous oxide will be $0·97 + 0·55 = 1·52$; (X.) shows that the weight of 100 cubic inches of nitrogen being 30·16 grains, and of 50 cubic inches oxygen being 17·05 grains, the weight of 100 cubic inches of nitrous oxide will be 47·21 grains.

THE various chemical apparatus and implements of the laboratory which are mentioned or described in this Work, may be obtained of Mr. Newman, 122, Regent Street; of Mr. Palmer, Newgate Street; of Messrs. Watkins and Hill, Charing Cross; and at Messrs. Knights', Foster Lane, Cheap-side.

CONTENTS.

PART THE FIRST.

	Page
HISTORICAL SKETCH OF THE ORIGIN AND PROGRESS OF CHEMICAL PHILOSOPHY.	
§ I. Definitions of Chemistry. Lord Bacon's advice to experimental Philosophers	1
§ II. Alchemy and Transmutation. Hermes Trismegistus; Geber; Roger Bacon; Albertus Magnus; Raymond Lully; Ripley, and others; the Narrative of Helvetius—of M. Gros; Ashmole's Theatrum Chemicum, Norton's Ordinall of Alchemy; Dr. Price; Peter Woulfe	5
§ III. Basil Valentine	18
§ IV. Paracelsus; Van Helmont; Lord Bacon; Glauber	22
§ V. Royal Society of London. Royal Academy of Paris. Boyle; Hooke	29
§ VI. Mayow; Newton; Geoffroy; Bergman, &c., on Affinity	36
§ VII. Invention of the Thermometer. Florentine Academicians; reflection and radiation of heat and cold	42
§ VIII. Hales; Boerhaave	46
§ IX. Black; Cullen; philosophy of heat; James Watt	53
§ X. Discoveries of Priestley	63
§ XI. Analytical Chemistry. Bergman; Vauquelin; Che- nevix, &c.	70
§ XII. Cavendish; Scheele; Lavoisier; Davy; Wollaston; Henry; Turner	78

CHAPTER I.

OF THE POWERS OF MATTER CONNECTED WITH CHEMICAL CHANGES	107
§ I. Attraction; aggregation; crystallization	107
§ II. Theories of crystallization	117

CHAPTER II.

	Page
HEAT, LIGHT, AND RADIANT MATTER	131
§ I. Expansion in general	131
§ II. Expansion of solids	132
§ III. Expansion of liquids	137
§ IV. Expansion of aëriform bodies and vapours	142
§ V. Determination of specific gravities	145
§ VI. Thermometers and pyrometers	147
§ VI. Conduction of heat	154
§ VII. Capacities for heat; specific heat	161
§ VIII. Effects of heat in changing the form of bodies; latent heat	165
§ IX. Liquifaction	166
§ X. Vaporization	172
§ XI. Theory of the steam-engine	186
§ XII. Radiant matter; reflection and refraction of light	188
§ XIII. Double refraction and polarization of light	194
§ XIV. Decomposition of light	197
§ XV. Chemical effects of the solar rays	199
§ XVI. Radiant matter as a source of heat	202
§ XVII. Terrestrial radiation; influence of various surfaces upon the reception and emission of radiant matter	202
§ XVIII. Phosphorescence	215
§ XIX. Effects of radiation in nature	219
§ XX. Ignition and combustion	221

CHAPTER III.

CHEMICAL ATTRACTION, OR AFFINITY	229
§ I. General results of chemical attraction	229
§ II. Theory of combination and decomposition	232
§ III. Chemical equivalents, and the atomic theory	234

CHAPTER IV.

ELECTRICITY	240
§ I. Electrical excitation; attraction and repulsion	241
§ II. Electrical conductors and non-conductors	244
§ III. Electroscopes and electrometers	246

	Page
§ IV. Induced electricity	248
§ V. Electrical machines	254
§ VI. General phenomena of electricity of tension	256
§ VII. Illustrations of electrical attraction, repulsion, and induction, and of the influence of points	259
§ VIII. Induction through glass; Leyden jar	262
§ IX. Electrophorus and condenser	269
§ X. Natural electrical phenomena	271
§ XI. Galvanism and Voltaic electricity	283
§ XII. Electrolysis	303
§ XIII. Source of Voltaic electricity, and theory of the pile .	319
§ XIV. Identity of Voltaic and common electricity . . .	323
§ XV. Animal electricity	327
§ XVI. Thermo-electricity	329
§ XVII. Magnetism	332
§ XVIII. Electro-magnetism	336
§ XIX. Magneto-electricity	343

CHAPTER V.

OF SIMPLE SUBSTANCES	348
§ I. Oxygen	358
§ II. Chlorine	362
§ III. Iodine	371
§ IV. Bromine	376
§ V. Fluorine	378
§ VI. Hydrogen	379
§ VII. Nitrogen	404
§ VIII. Sulphur	457
§ IX. Phosphorus	482
§ X. Selenium	502
§ XI. Carbon	508
§ XII. Boron	579

§ XLIII. Silicium	1026

PART THE THIRD.

CHAPTER VII.

	Page
VEGETABLE PRODUCTS	1043
§ I. Of the growth, structure, and functions of plants	1043
§ II. Of the composition and analysis of vegetable substances, and of their ultimate principles	1053
§ III. Gum, mucilage, and their varieties; pectin and pectic acid; mucic and pyromucic acid	1068
§ IV. Sugar: cane sugar, honey sugar, grape sugar. Mannite. Liquorice sugar, or glycyrrhizin. Mushroom sugar	1073
§ V. Starch and its varieties. Inulin, lichenin, &c.	1083
§ VI. Gluten and albumen	1091
§ VII. Lignin	1094
§ VIII. Vegetable extract. Ulmin	1098
§ IX. Astringent extractive; tannin; tannic acid; gallic acid; ellagic acid; pyrogallic acid; metagallic acid	1101
§ X. Colorific extractive. Colouring matter	1110
§ XI. Fixed or fat oils. Wax.	1128
§ XII. Soaps. Saponic or adipose acids	1135
§ XIII. Volatile oils; camphene; camphor; camphoric acid; citrene; oil of copivi	1143
§ XIV. Benzule; benzoic acid; amygdaline; cinnamule	1149
§ XV. Resins; amber; caoutchouc	1157
§ XVI. Bitumens; coal; tar, &c.	1163
§ XVII. Vegetable acids	1170
§ XVIII. Vegetable alkaloids, and substances associated with, or allied to them	1199
§ XIX. Crystallizable and other principles not salifiable, but in some respects analogous to the alkaloids	1231
§ XX. Parts of plants	1241
§ XXI. Phenomena and products of vinous fermentation. Alcohol	1256

§ XXII. Ether	Page 1274
§ XXIII. Combinations of ether, and of etherine or quadri- hydrocarbon, with the oxyacids	1287
§ XXIV. Combinations of ethule with halogens, or of etherine with the hydracids	1303
§ XXV. Acetous fermentation; vinegar; acetic acid; methy- lene; aldehyd	1308

CHAPTER VIII.

ANIMAL PRODUCTS	1332
§ I. Of the blood	1337
§ II. Milk	1353
§ III. Bile; biliary concretions	1364
§ IV. Saliva; pancreatic juice; gastric juice; lymph; mucus; pus	1367
§ V. Urine; urea; uric acid; urinary calculi	1371
§ VI. Soft solids of animals; skin; gelatin; muscle, &c.	1394
§ VII. Animal fat	1399
§ VIII. Shell and bone	1407
§ IX. Animal functions	1409

APPENDIX.

II. French weights and measures	1418
GENERAL INDEX	1421

HISTORICAL SKETCH OF THE ORIGIN AND PROGRESS

OF

CHEMICAL PHILOSOPHY.

§ I.

CHEMISTRY is that branch of natural knowledge which teaches us the properties of the elementary substances, and of their mutual combinations; it inquires into the laws which affect, and into the powers which preside over their union; it examines the proportions in which they combine, and the modes of separating them when combined; and endeavours to apply such knowledge to the explication of natural phenomena, and to useful purposes in the arts of life*.

Chemistry cannot be said to have existed, as a science, previous to the commencement of the seventeenth century; for although we find, in the writings of the earlier chemists, many curious and important facts and discoveries, these remained useless and unapplied, so long as the minds of men were exclusively directed to the transmutation of the metals, the composition of an universal elixir, and the production of the *Alcahest*, or general solvent. Although, therefore, it may often be amusing, and sometimes profitable, to revert to the crude speculations and waking dreams of the voluminous writers upon these subjects, who were eminent in the fourteenth and two successive centuries, the time of the student will be more usefully occupied in tracing the labours of those who, discarding visionary hypotheses, proceeded to the investigation of truth;

* *Definitions of Chemistry.*—"La Chymie est un art qui enseigne à séparer les différentes substances qui se rencontrent dans un mixte." L'EMERY, *Cours de Chymie*.

"Chemistry is that science which examines the constituent parts of bodies, with reference to their nature, proportions, and method of combination." BERGMAN, *Essay on the Usefulness of Chemistry*.

"Chemistry is the study of the effects of heat and mixture, with a view of discovering their general and subordinate laws, and of improving the useful arts." BLACK, *Lectures*.

"La Chimie est une science qui apprend à connaître l'action intime et réciproque de tous les corps de la nature, les uns sur les autres. Par les mots *action intime*, et *reciproque*, cette science est distinguée de la physique expérimentale, qui ne considère que les propriétés extérieures des corps doués d'un volume,

et d'une masse qu'on peut mesurer, tandis que la Chimie ne s'attache qu'aux propriétés intérieures, et n'agit que sur des molécules, dont le volume et la masse ne peuvent pas être soumis aux mesures et aux calculs." FOURCROY, *Système des Connoissances Chimiques*, vol. i., p. 4.

"Die Chemie ist eine Wissenschaft die uns die wechselseitige wirkungen der einfachern Stoffe in der Natur, die zusammensetzung der körper aus ihren und nach ihren verschiedenen verhältnissen, und die Art und Weise kennen lehrt, sie zu trennen, oder sie wieder zu neuen Körperarten zu verbinden." GREN. *Systematisches handbuch der Chemie*, p. 1. Halle, 1794.

"Chemistry is that science which treats of those events or changes in natural bodies, which are not accompanied by sensible motions." THOMSON, *System of Chemistry*, 5th edition, p. 2.

"Most of the substances belonging to our globe are constantly undergoing

and who were led on, not by the vague glimmering of speculative notions, but by the steady daylight of real philosophy*.

It is, I think, among our own countrymen that we discover the fathers of chemical philosophy: for BACON, BOYLE, HOOKE, MAYOW, and NEWTON, present unequivocal claims to that distinctive title. As induction from experiment is exclusively the basis of chemical science, little progress could be made in it till the futility of the ancient philosophical systems had been shown, and their influence annihilated; till the true end of science was rightly defined, [and the road to it rendered straight and passable; till the necessity of well-digested experiment had been established, which "first procures the light, then shows the way by its means."

It may seem trite to quote Lord BACON; but, as experience is constantly showing the neglect of the invaluable doctrines inculcated in his

alterations in sensible qualities, and one variety of matter becomes, as it were, transmuted into another. Such changes, whether natural or artificial, whether slowly or rapidly performed, are called chemical; thus the gradual and almost imperceptible decay of the leaves and branches of a fallen tree exposed to the atmosphere, and the rapid combustion of wood in our fires, are both chemical operations.

"The object of chemical philosophy is to ascertain the causes of all phenomena of this kind, and to discover the laws by which they are governed." DAVY, *Elements of Chemical Philosophy*, p. 1.

In the latest editions of Johnson's *Dictionary*, the erroneous and antiquated definition of Boerhaave is very improperly retained. "An art whereby sensible bodies, contained in vessels, or capable of being contained therein, are so changed by means of certain instruments, and principally fire, that their several powers and virtues are thereby discovered, with a view to philosophy or medicine."

The derivation of the word Chemistry can scarcely be said to have been ascertained. The most plausible guesses are the following: from *χυνω*, to melt, or *χυμος*, juice; from *kema*, an oriental word signifying *black*; from *Χημης*, the name of a person eminently skilled in the sciences; from *Chémi*, the Coptic name of Egypt, where the art is supposed to have had its rise.

According to Bryant (*Ancient Mythol.*), it is derived from *chemia*, and that word from *Cham*.

The Rev. Mr. Palmer, Professor of Arabic at Cambridge, has given the following etymology: "Al-chemy, or

more properly Al-kemy, the knowledge of the substance or composition of bodies, so named from the substantive (Kya-mon), that is the substance or constitution of anything; from the root (Kama.) Golius. *Lexicon*." THOMSON'S *Chemistry*, 5th edit., p. 4, Note.

Conversing upon this subject with my late friend, Dr. Thomas Young, he remarked, that the Egyptians probably neither knew nor cared much about the composition of bodies; and that the term Chemistry, as referring to the secret art of transmutation, was probably derived from the Coptic root *hheims* or *chems*, signifying *obscure*, *dark*. The German word *geheim*, *secret*, he said, was perhaps of the same root.

"Hæc ars varia accepit nomina, nam omnium primò dicta fuit τέχνη ποιητική, et antiquis illis temporibus per hanc vocem significabant artem villa metalla in aurum convertendi, et ejus artifices ποιηταί vocari Zozimus dicit. Veteres Ægyptios hanc artem Chimoet vocasse Josephus Scaliger ibi ostendit, sed postea Græci hanc artem χυμοποιαν dixerunt, Arabibus vero, Alchemia." BOERHAAVE, *Institutiones Chemicæ*.

* "Tout ce qu'on a dit de l'antique origine de la Chimie, sur les premiers hommes qui ont travaillé les métaux, taillé et poli les pierres dures, fondu les sables, dissous et cristallisé les sels, ne montre à un esprit exact et sévère qu'une vaine et ridicule prétension, semblable à cette par laquelle on voudrait reconnoître les élémens de la géométrie dans l'ouvrage grossier du sauvage qui use les fragmens du rocher, qui leur donne des formes à peu près régulières pour les rendre utiles à ses premiers besoins." FOURCROY, *Discours Préliminaire*.

works, and as students, especially, are too apt to throw off the burden and responsibility of thinking for themselves, by adopting the notions of others, without duly weighing their merit or appreciating their correctness, and often only because they are new, I shall call their attention to one of the many relevant passages of this author:—

“He who would come duly prepared, and fitted to the business of interpretation, must neither be a follower of novelty, custom, nor antiquity; nor indulge himself in a liberty of contradicting; nor servilely follow authority. He must neither be hasty in affirming, nor loose and sceptical in doubting; but raise up particulars to the places assigned them by their degree of evidence and proof. His hope must encourage him to labour, and not to rest; he must not judge of things by their uncommon nature, their difficulty, or their high character; but by their just weight and use. He must, in his own particular, carry on his view with concealment, and yet have a due regard for posterity. He must prudently observe the first entrance of errors into truths, and of truths into errors, without despising or admiring anything. He must understand his own talents and abilities, or the advantages of his own nature. He must comply with the nature of others. He must, as with one eye, survey the natures of things, and have the other turned towards human uses. He must distinctly understand the mixed nature of words, which is extremely capable both of prejudicing and assisting. He must lay it down to himself, that the art of discovering will grow up, and improve, along with discoveries themselves. He must not be vain either in delivering or concealing the knowledge he has acquired, but ingenuous and prudent, and communicate his inventions without pride or ill-nature: and this in a strong and lively manner, well defended against the injuries of time, and fit for the propagation of knowledge, without occasioning errors; and, which is the principal thing of all, it must be such as may select and choose for itself a prepared and suitable reader*.”

The following observations, from the same source, bring us back to our subject:—

“And again; if any one should condescend to regard such things as are accounted rather curious than useful, and take a thorough view of the works of the alchymists, or the followers of natural magic, he might, perhaps, be at a difficulty which he should withhold, his tears, or his laughter. For the alchymist goes on with an eternal hope; and where his matters succeed not, lays the blame upon his own errors; and accuses himself as not having sufficiently understood either the terms of his art, or his author: whence he either hearkens out for traditions and auricular whispers, or else fancies he made some mistake as to the exact quantity of the ingredients, or nicety of the experiment; and thus repeats the operation without end. And if, in the mean time, among all the chances of experiments, he throws any which appear either new or useful, he feeds his mind with these as so many earnest; boasts and extols them above measure; and conceives great hopes of what is behind. It must, indeed, be allowed that the alchymists have made many discoveries, and obliged mankind with useful inventions; but they are well represented in that fable of the old man, who left an estate to his children, buried

* *Prefatory Aphorisms of the Novum Organum Scientiarum.* No. XI.

somewhere or other, he told them, in his vineyard; which they, therefore, fell to dig for with great diligence; whereby, though they found no gold in substance, yet they received a better vintage for their labour.

"But such as apply to natural magic, and explain everything by sympathies and antipathies, have, by supine and indolent conjectures, placed strange virtues and operations in things; and if, at any time, they have produced works, they are rather suited to admiration and strangeness, than to fruit and advantage*."

It is my intention, in this introductory chapter, after a brief allusion to the style and views of the alchemical writers, to notice the principal researches of the chemists of the fifteenth and two following centuries; and thus to give an historical sketch of the science, from its early days, to the commencement of the present age.

In reference to the ends and objects of chemical science, under its present aspect, I cannot do better than quote our modern Bacon, from whose *Discourse on the Study of Natural Philosophy*, I shall be content with the following extract, earnestly advising all students steadily to peruse and consider that excellent and sensible essay:—

"The laws," says Sir F. W. HERSCHEL, "which concern the intimate constitution of bodies, not as respects their *structure* or the manner in which their parts are put together, but as regards their *materials* or the ingredients of which those parts are composed, form the objects of chemistry. A solid body may be regarded as a fabric, more or less regularly and artificially constructed, in which the materials and the workmanship may be separately considered, and in which, though the latter be ruined and confounded by violence, the former remain unchanged in their nature, though differently arranged. In liquid or aerial bodies, too, though there prevails a less degree of difference in point of structure, and a greater facility of dispersion and dissipation, than in solids, yet an equal diversity of *materials* subsists, giving to them properties differing extremely from each other.

"The inherent activity of matter is proved not only by the production of motion by the mutual attractions and repulsions of distant or contiguous masses, but by the changes and apparent transformations which different substances undergo in their sensible qualities by mere mixture. If water be added to water, or salt to salt, the effect is an increase of quantity, but no change of quality. In this case, the mutual action of the particles is entirely mechanical. Again, if a blue powder and a yellow one, each perfectly dry, be mixed and well shaken together, a green powder will be produced: but this is a mere effect arising in the eye from the intimate mixture of the yellow and blue light separately and independently reflected from the minute particles of each; and the proof is had by examining the mixture with a microscope, when the yellow and blue grains will be seen separate and each quite unaltered. If the same experiment be tried with coloured liquids, which are susceptible of mixing without chemical action, a compound colour is likewise produced, but no examination with magnifiers is in that case sufficient to detect the ingredients; the reason obviously being, the excessive minuteness of the parts, and their perfect intermixture, produced by agitating

* *Novum Organum*, Section V.

two liquids together. From the mixture of two powders, extreme patience would enable any one, by picking out with a magnifier grain after grain, to separate the ingredients. But when liquids are mixed, no mechanical separation is any longer practicable; the particles are so minute as to elude all search. Yet this does not hinder us from regarding such a compound as still a mere mixture, and its properties are accordingly intermediate between those of the liquids mixed. But this is far from being the case with all liquids. When a solution of potash, for example, and another of tartaric acid, each perfectly liquid, are mixed together in proper proportions, a great quantity of solid saline substance falls to the bottom of the containing vessel, which is quite different from either potash or tartaric acid, and the liquid from which it subsided offers no indications by its taste or other sensible qualities of the ingredients mixed, but of something totally different from either. It is evident that this is a phenomenon widely different from that of mere mixture; there has taken place a great and radical change in the intimate nature of the ingredients, by which a new substance is produced which had no existence before. And it has been produced by the *union* of the ingredients presented to each other; for when examined it is found that nothing has been *lost*, the weight of the whole mixture being the sum of the weights mixed. Yet the potash and tartaric acid have disappeared entirely, and the weight of the new product is found to be exactly equal to that of the tartaric acid and potash employed, taken together, abating a small portion held in solution in the liquid, which may be obtained, however, by evaporation. They have therefore combined, and adhere to one another with a cohesive force sufficient to form a solid out of a liquid; a force which has thus been called into action by merely presenting them to each other in a state of solution.

“It is the business of chemistry to investigate these and similar changes, or the reverse of such changes, where a single substance is resolved into two or more others, having different properties from it, and from each other, and to inquire into all the circumstances which can influence them; and either determine, modify, or suspend their accomplishment, whether such influence be exercised by heat or cold, by time and rest, or by agitation or pressure, or by any of those agents of which we have acquired a knowledge, such as electricity, light, magnetism, &c.”

§ II.

THE transmutation of baser metals into gold and silver, which was the chief, and, in most cases, the only object of the genuine alchemists, was not merely regarded as possible, but believed to have been performed, by some of the more enlightened chemists of the seventeenth century; and in perusing the history of these transmutations, as recorded by HELVETIUS, BOERHAAVE, BOYLE, and other sober-minded men, it would be difficult to resist the evidence adduced, without the aids of modern science. Lord BACON'S sound sense has been arraigned for his belief in alchemy, though he, in fact, rather urges the possibility than the probability of transmutation; and, considering the infant state of the experimental sciences, and of chemistry in particular, in his age, and the plausible

exterior of the phenomena that the chemists were able to produce, he is rather to be considered as sceptical than credulous, upon many of the points which he discusses.

HERMES TRISMEGISTUS, who is said to have lived in the year of the world 2076, has generally been quoted as the oldest of the alchemists; there can, however, be very little doubt that the writings attributed to him are entirely spurious. The *Tractatus Aureus*, or *Golden Work*, is evidently a farrago of occult philosophy belonging to a much later period. HERMES, at the outset, is made to apologize for divulging the secrets of the black art. "I should never have revealed them," says he, "had not the fear of eternal judgment, or the hazard of the perdition of my soul, prevailed with me, for such a concealment. It is a debt I am willing to pay to the just, even as the Father of the just liberally bestowed it upon me." After this prelude, we might expect to be let into some of the mysteries of alchemy, but our curiosity is quickly disappointed, by finding that they are only revealed to the eyes and ears of the sons of art; "not to the profane, the unworthy, and the scoffers, who, being as greedy dogs, wolves, and foxes, are not to feed at our divine repast." The reader is then conducted into what is termed the *innermost chamber*, and regaled with a history and explanation of various matters relating to the philosopher's stone, by means of which, "through the permission of the Omnipotent, the greatest disease is cured, and sorrow, distress, evil, and every hurtful thing evaded; by help of which we pass from darkness to light, from a desert and wilderness to a habitation and home, and from straitness and necessities to a large and ample estate." We are then directed to "catch the flying bird," by which is meant quicksilver; "and drown it so that it may fly no more;" this is what is afterwards termed the *fixation* of mercury, by uniting it to gold. It is then to be plunged into the "well of the philosophers," or *aqua regia*, "by which its soul will be dissipated, and its corporeal particles united to the "red eagle," or muriate of gold.

GEBER is another great name in the history of alchemy*; the exact period at which he lived is unknown, but it was probably not later than the seventh century. Whatever may be the date or the authenticity ascribed to the works bearing the name of GEBER, they are among the oldest chemical treatises in existence, and merely as such deserve the perusal of the historian. His three books of alchemy were published at Strasburgh, in 1520, and, if genuine, contain matter that justifies the praise of BOERHAAVE, who considers him as a first-rate philosopher of his age. In his chapter *On the Alchemie of Sol*, after descanting upon the different means of refining and dissolving gold, he describes several solar

* "Primus omnium Arabum post Græcos est Geber, cui dant titulum Arabis. Alii dicunt eum fuisse regem, unde *rex Geber Arabs*, dici solet; sed *Leo Africanus*, qui Græcus fuit et multa descripsit ex antiquis Arabibus, dicit Gebrum illum natione Græcus fuisse, sed derogasse suam religionem, et se dedisse Mahomedæ religioni Arabum, et vixisse septimo seculo." BOERHAAVE.

Geber was also a physician and astronomer. The following are the principal works on chemistry which have been attributed to him: *De Alchemia*,—*De summa Perfectione Metallorum*,—*De Lapide Philosophico*,—*De inveniendi Arte Auri et Argenti*. These, and some other works bearing his name, whether genuine or not, furnish good specimens of the early alchemical writings.

medicines in language which is tolerably intelligible; they are all solutions of gold in nitro-muriatic acid, with the addition of quicksilver, nitre, common salt, and some other saline matters. The student is directed to prepare his mind for his pursuits by suitable acts of piety and charity, which, if earnestly and perseveringly carried on, may, after due time, enable him, "to change argent vive into an infinite solific and lunific, without the help of anything more than its multiplication." Alembics, crucibles, and various furnaces are so fully described, and, if we may believe the MSS., depicted by GEBER, that he deserves to be mentioned also as the inventor of much useful apparatus. Some have asserted his pretensions to the possession of the universal medicine, for he speaks of curing disease; but this seems a mere metaphorical expression, relating to transmutation. "Bring me," says he, "the six lepers, that I may cleanse them;" by which he probably would imply the conversion of silver, mercury, copper, iron, tin, and lead, into gold; these seven metals only having been known at that period. Dr. Johnson supposes that the word *Gibberish*, anciently written *Geberish*, was originally applied to the language of Geber and his tribe.

ARTEPHIUS, in 1130, published several alchemical tracts: we are told by ROGER BACON and others, that he died at the age of 1025, having prolonged his life by the miraculous virtues of his medicines; but his name, and that of JOHN DE RUPESCISSA, are now deservedly forgotten.

The alchemical annals of the thirteenth century are adorned by the name of ROGER BACON, a native of Ilchester, in Somersetshire, and descended from an ancient and honourable family. In 1240, he returned from Paris, and became celebrated among the learned of the University of Oxford. At that time, however, the exposition of ignorance, and attempts to overthrow the dogmas of the schools, was a service of risk and danger; and to this Friar BACON, for he was a monk of the Franciscan order, laid himself fully open: he was accused of practising witchcraft, thrown into prison, and nearly starved, for exposing the prevalent immorality of the clergy; and, according to some, stood a chance of being burned as a magician.

I know of no work that strikes one with more surprise than the *Opus Majus* of ROGER BACON; he stands alone like a beacon upon a waste; he is perspicuous and comprehensive; and full of anticipations of the advantages likely to be derived from the mode of investigation insisted upon by his great successor, Chancellor BACON. This resemblance between ROGER BACON and his illustrious namesake has scarcely been noticed by the historians of his period; it has, however, not escaped Mr. HALLAM'S observation, who adverts to it in his *History of the Middle Ages*. Whether Lord BACON, he says, "ever read the *Opus Majus*, I know not; but it is singular, that his favourite quaint expression, *prærogative scientiarum*, should be found in that work; and whoever reads the sixth part of the *Opus Majus*, upon experimental science, must be struck by it as the prototype in spirit of the *Novum Organum*. The same sanguine and sometimes rash confidence in the effect of physical discoveries; the same fondness for experiment; the same preference of inductive to abstract reasoning, pervade both works."

The alchemical work of ROGER BACON which has been most prized, is the *Mirror of Alchymy*, but there is little either of interest or entertainment to be extracted from it*.

ROGER BACON has by some been spoken of as a benefactor to mankind, by others as an enemy to the human race, inasmuch as he is plausibly considered to have invented gunpowder†, an invention by which the personal barbarity of warfare has certainly been diminished, "but which, considered as an instrument of human destruction, by far more powerful than any that skill had devised, or accident presented, before; acquiring, as experience shows us, a more sanguinary dominion in every succeeding age, and borrowing all the progressive resources of science and civilization for the extermination of mankind, appals us," says Mr. HALLAM, "at the future prospects of the species, and makes us feel, perhaps more than in any other instance, a difficulty in reconciling the mysterious dispensation with the benevolent order of Providence."

This discovery has sometimes been given to BARTHOLOMEW SCHWARTZ, a German monk, and the date of 1320 annexed to it, a date posterior to that which may be justly claimed for Friar BACON. Upon the authority, however, of an Arabic writer in the Escorial collection, referred to by Mr. HALLAM, there seems little reason to doubt that gunpowder was introduced, through the means of the Saracens, into Europe, before the middle of the fifteenth century, though its use in engines of war was probably more like that of fireworks than artillery. Many authorities might be adduced to prove the common use of gunpowder early in the fourteenth century. EDWARD THE THIRD employed artillery with memorable effect at the battle of Cressy; and, in the fifteenth century, hand-cannons and muskets came into use, and gunpowder was in common employ.

ALBERT OF COLOGNE, surnamed THE GREAT, was a contemporary of ROGER BACON; he is celebrated as the inventor of the *brazen head*, which

* Gmelin has given the following list of the chemical writings of Roger Bacon. The two first are given in Mangetus.

1. Speculum Alchymiaë.
2. Epistola de Secretis Operibus Artis et Naturæ, et de Nullitate Magiæ.
3. De Mirabili Potestate Artis et Naturæ.
4. Medulla Alchymiaë.
5. De Arte Chemiæ.
6. Breviarium Alchymiaë.
7. Documenta Alchymiaë.
8. De Alchymistarum Artibus.
9. De Secretis.
10. De Rebus Metallicis.
11. De Sculpturis Lapidum.
12. De Philosophorum Lapide.
13. Opus Majus, or Alchymia Major.
14. Breviarium de Dono Dei.
15. Verbum Abbreviatum de Leone Viridi.
16. Secretum Secretorum.

17. Tractatus Trium Verborum.
18. Speculum Secretorum.

† "From saltpetre and other ingredients," says Roger Bacon, "we are able to form a fire which will burn to any distance." And again, alluding to its effects, "a small portion of matter about the size of the thumb, *properly disposed*, will make a tremendous sound and concussion, by which cities and armies might be destroyed." And again, in the same work, is a passage which, though somewhat enigmatical, is supposed to divulge the secret of this preparation. "*Sed tamen salis petraë, luru mone cap ubre, et sulphuris, et sic facies tonitrum si scias artificium.*" The anagram is convertible into *carbonum pulvere*. Such are the claims of Roger Bacon to a discovery which soon changed the whole art of war.

was demolished by the pious zeal of his pupil, the angelical Dr. Aquinas*, in consequence of his suspecting it to be an agent of the devil. ALBERTUS MAGNUS was what in our days is termed an universal genius. He is chiefly celebrated as the commentator of ARISTOTLE; but, if we give credit to contemporary writers, he was deeply skilled in all the higher departments of alchemical philosophy. His works, which are very voluminous, were published at Leyden, in 1651, by Peter Jammy. They fill twenty-one folio volumes. Most of his alchemical tracts have been inserted in the *Theatrum Chemicum*.

The names of RAYMOND LULLY of Majorca, and ARNOLD of Villanovat, occur in this page of the history of chemical science. Their merit, however, consists rather in the quantity than quality of their writings. LULLY died on his passage from Africa in 1315, whither he had been to preach the truths of the Gospel; his body was carried to Majorca, where he was honoured as a martyr. BRUCKER says, "he was more ingenious than honest." His chemical opinions are scarcely worth quotation or abstract. He is said to have converted iron into gold in the presence of EDWARD THE FIRST in London, which was coined into rose-nobles†.

ARNOLD shines as a magician and astrologer. He was a renowned prophet, and predicted that the world would come to an end in the year 1376. He was shipwrecked on the coast of Genoa, in 1313.

ISAAC and JOHN of Holland were also alchemical philosophers of this period§.

About the year 1560, a *Treatise of Alchymy* was published at Paris, attributed to NICHOLAS FLAMMEL. The work, however, is spurious, and was merely ascribed to him from his becoming suddenly, as it is said, very rich. The use he made of his wealth does his memory much credit: he founded hospitals, repaired churches, and endowed several charitable institutions; proceedings which by no means savour of alchemy. Dr. SALMON, who in 1692 published one of the above-mentioned tracts, says, "FLAMMEL was originally a poor scrivener, yet left so great monuments behind him, as must convince the most incredulous that he knew the secret; and performed such mighty works at his own proper cost and charges, as the most opulent prince in Europe can never do the like. I know," says he, "a gentleman who went to view those mighty buildings and their records. The archives and governors of those places, he told me, own the matter of fact, but deny the means, saying, that FLAMMEL was a very pious man, and went a pilgrimage to St. James of Gallicia,

* Thomas Aquinas wrote several works on alchemy. "So far as I have perused them," says Dr. Thomson, "they are exceedingly obscure, and in various places unintelligible. Some of the terms, still employed by modern chemists, occur for the first time in his writings. Thus the term *amalgam*, still employed to denote a compound of mercury with another metal, occurs in them. I have not observed it in any earlier author."

† Raymond Lully was born in Majorca,

in 1236, and Arnold of Villanova in Provence, in 1235.

‡ BERGMAN, *Histor. Chem.*

§ "Sequuntur nunc Johannes et Isaacus Hollandus, pater et filius, qui diffusissimo sermone et magnâ eloquentiâ scripserunt, et si unum vel alterum arcanum exceperis pulcherrima experimenta fecerunt de sanguine et urinâ humanâ, quæ Helmontius postea et Boyleus pro recentioribus inventis habuerunt."—BOERHAAVE.

for a reward of which piety the holy saint bestowed that vast treasure upon him by way of miracle; thereby denying the power of art by which it was certainly effected, to establish a miracle performed by the Romish saint." He was moreover celebrated for his hieroglyphics, of which fac-similes are given in SALMON's edition. They are much of the same cast as those that now adorn MOORE's *Almanac*, and quite as edifying.

In SALMON's collection we find the *Marrow of Alchymy*, by GEORGE RIPLEY, *Chanon of Bridlington in Yorkshire*, who was a chemist perhaps less deserving of the reputation he acquired than most of his compeers. He may be quoted as a chemical poet. His *Compound of Alchemie*, dedicated to EDWARD THE FOURTH, is rugged enough, but not unintelligible. The following stanzas from the preface of this piece, given in ASHMOLE's *Theatrum Chemicum Britannicum*, will afford a fair idea of RIPLEY's merits as a poet and philosopher:—

But into Chapters thys Treatis I shall devyde,
In number twelve, with dew recapitulatyon;
Superfluous rehearsalls I lay asyde,
Intendyng only to give trew informatyon,
Both of the theoryke and practycall operatyon:
That by my wrytyng who so wyll guyded be,
Of hys intente perfectly speed shall he.

The fyrst chapter shall be of naturall *Calcination*;
The second of *Dyssolution*, secret and phylosophycall;
The third of our elementall *Separation*;
The fourth of *Conjunction* matrimoniall;
The fyfth of *Putrefaction* then followe shall:
Of *Congelation* *Albyficative* shall be the sixt,
Then of *Cybatation*, the seaventh shall follow next.

The secret of our *Sublymation* the eyght shall show;
The nynth shall be of *Fermentatyon*;
The tenth of our *Exaltation* I trow.

The-elevent of our mervelose *Multiplycatyon*,
The twelfth of *Projection*, then *Recapitulatyon*,
And so this treatise shall take an end,
By the help of God, as I entend.

Thus here the Tract of Alchemie doth end;
Which tract was by George Ripley, Chanon, penn'd.

It was composed, writt, and signed his owne,
In anno twice seaven hundred seaventy-one.

Reader, assist him, make it thy desire
That after lyfe he may have gentle fire!—AMEN.

The degree of faith placed in alchemy was of course much shaken by the multiplied experiments which were undertaken during the seventeenth century; in general, however, those who failed attributed their ill success to any rather than the real cause. SALMON's creed is that of most of his contemporaries. "As to the great and philosophic work," says he, (meaning transmutation,) "it is my opinion and belief, that there is such a thing in nature. I know the matter of fact to be true, though the way and manner of doing it is as yet hid from me. I have been eye-witness of so much as is able to convince any man endued with rational faculties, that there is a possibility of the transmutation of metals; yet, for all these things, will not advise any man, ignorant of the power of nature and the

way of operation, to attempt the work, lest, erring in the foundation, he should suffer loss, and blame me. Without doubt it is a gift of God from above, and he that attains it must patiently wait the moving of the waters; when the destined angel moves the waters of the pool, then is the time to immerge the leprous metal, and cleanse it from all impurities."

VAN HELMONT says, "I am constrained to believe in the making of gold and silver, though I know many exquisite chemists to have consumed their own and other men's goods in search of this mystery; and to this day we see these worthy and simple labourers cunningly deluded by a diabolical crew of gold and silver sucking-flies and leeches. But I know that many will contradict this truth; one says it is the work of the devil, and another that the sauce is dearer than the meat."

BERGMAN, in summing up the evidence for and against the possibility and probability of transmutation, and founding his opinion upon the multitude of relations that have been handed down to us by different writers of apparent veracity, one or two of which I shall presently quote, observes that "although most of them are deceptive, and many uncertain, some bear such character and testimony, that, unless we reject all historical evidence, we must allow them entitled to confidence*."

For my own part, the perusal of the histories of transmutation appears to me to furnish solid ground for a diametrically opposite opinion. They are all of a most suspicious character; sometimes the fraud was open and intentional, seconded by juggling dexterity; at other times the performers deceived themselves: they purchased what was termed a *powder of projection*, prepared by the adepts, containing a portion of gold; and when they threw it into the fire with mercury, and found that portion of gold remaining in their crucible, they mistook its source. But the cases which are quoted as least exceptionable, are often exactly those which are really impossible; namely, where the weight of the powder of projection, and of the lead or other base metal taken conjointly, was exceeded by that of the gold produced. Such is HIERNES' history of PAYKUL's transmutation, who, with six drachms of lead and one of powder, produced an ingot that was coined into one hundred and forty-seven ducats; and many others. But the most celebrated history of transmutation is that given by HELVETIUS, in his *Brief of the Golden Calf; discovering the rarest Miracle in Nature, how by the smallest portion of the Philosopher's Stone a great Piece of Common Lead was totally transmuted into the purest transplendent Gold, at the Hague, in 1666*; and, as it is a luminous epitome of all that has been done on this subject, I shall briefly abridge the proceedings:—

"The 27th day of December, 1666, in the afternoon, came a stranger to my house at the Hague, in a plebeick habit, of honest gravity and serious authority, of a mean stature and a little long face, black hair not at all curled, a beardless chin, and about forty-four years (as I guess) of age, and born in North Holland. After salutation, he beseeched me with great reverence to pardon his rude accesses, for he was a lover of the Pyrotechnian art, and having read my treatise against the sympathetic powder of Sir KENELM DIGBY, and observed my doubt about the philosophic mystery, induced him to ask me if I really was a disbeliever as to

* *Opuscula*, iv. 127.

the existence of an universal medicine which would cure all diseases, unless the principal parts were perished, or the predestinated time of death come. I replied, I never met with an adept, or saw such a medicine, though I had fervently prayed for it. Then I said, surely you are a learned physician. No, said he, I am a brass-founder, and a lover of chemistry. He then took from his bosom-pouch a neat ivory box, and out of it three ponderous lumps of stone, each about the bigness of a walnut. I greedily saw and handled for a quarter of an hour this most noble substance, the value of which might be somewhere about twenty tons of gold; and having drawn from the owner many rare secrets of its admirable effects, I returned him this treasure of treasures with a most sorrowful mind, humbly beseeching him to bestow a fragment of it upon me in perpetual memory of him, though but the size of a coriander seed. No, no, said he, that is not lawful, though thou wouldest give me as many golden ducats as would fill this room; for it would have particular consequences, and if fire could be burned of fire, I would at this instant rather cast it all into the fiercest flames. He then asked if I had a private chamber whose prospect was from the public street; so I presently conducted him to my best furnished room backwards, which he entered," says HELVETIUS, (in the true spirit of Dutch cleanliness,) "without wiping his shoes, which were full of snow and dirt. I now expected he would bestow some great secret upon me, but in vain. He asked for a piece of gold, and opening his doublet showed me five pieces of that precious metal which he wore upon a green riband, and which very much excelled mine in flexibility and colour, each being the size of a small trencher. I now earnestly again craved a crumb of the stone, and, at last, out of his philosophical commiseration, he gave me a morsel as large as a rape-seed; but I said, this scanty portion will scarcely transmute four grains of lead. Then, said he, deliver it me back: which I did, in hopes of a greater parcel; but he, cutting off half with his nail, said, Even this is sufficient for thee. Sir, said I, with a dejected countenance, what means this? And he said, even that will transmute half an ounce of lead. So I gave him great thanks, and said I would try it, and reveal it to no one. He then took his leave, and said he would call again next morning at nine. I then confessed, that while the mass of his medicine was in my hand the day before, I had secretly scraped off a bit with my nail, which I projected on lead, but it caused no transmutation, for the whole flew away in fumes. Friend, said he, thou art more dexterous in committing theft than in applying medicine; hadst thou wrapt up thy stolen prey in yellow wax, it would have penetrated and transmuted the lead into gold. I then asked if the philosophic work cost much or required long time, for philosophers say that nine or ten months are required for it. He answered, Their writings are only to be understood by the adepts, without whom no student can prepare this magistry. Fling not away, therefore, thy money and goods in hunting out this art, for thou shalt never find it. To which I replied, As thy master showed it thee, so mayest thou perchance discover something thereof to me, who know the rudiments, and therefore it may be easier to add to a foundation than begin anew. In this art, said he, it is quite otherwise; for unless thou knowest the thing from head to heel, thou canst not break

open the glassy seal of HERMES. But enough; to-morrow, at the ninth hour, I will show thee the manner of projection. But ELIAS never came again; so my wife, who was curious in the art whereof the worthy man had discoursed, teased me to make the experiment with the little spark of bounty the artist had left me; so I melted half an ounce of lead, upon which my wife put in the said medicine; it hissed and bubbled, and in a quarter of an hour the mass of lead was transmuted into fine gold, at which we were exceedingly amazed. I took it to the goldsmith, who judged it most excellent, and willingly offered fifty florins for each ounce." Such is the celebrated history of ELIAS THE ARTIST and Dr. HELVETIUS.

Sir KENELM DIGBY, whose name is mentioned in this narrative, was a renowned dabbler in the mysterious art. Under the date of seventh November, 1651, in EVELYN'S *Diary**, "He gave me," says Mr. EVELYN, "a certain powder, with which he affirmed that he had fixed mercury before the late king. He advised me to try and digest a little better, and gave me a water which he said was only rain water, of the autumnal equinox, exceedingly rectified and very volatile: it had a taste of strong vitriolic, and smelt like aquafortis. He intended it for a dissolvent of calx of gold; but the truth is, Sir KENELM was an arrant mountebank."

The following is another history of transmutation, given by Mangetus (Preface to the *Bibliotheca Chemica Curiosa*), on the authority of M. Gros, a clergyman of Geneva, "of the most unexceptionable character, and at the same time a skilful physician and expert chemist."

"About the year 1650 an unknown Italian came to Geneva, and took lodgings at the sign of the *Green Cross*. After remaining there a day or two, he requested De Luc, the landlord, to procure him a man acquainted with Italian, to accompany him through the town and point out those things which deserved to be examined. De Luc was acquainted with M. Gros, at that time about twenty years of age, and a student in Geneva, and knowing his proficiency in the Italian language, requested him to accompany the stranger. To this proposition he willingly acceded, and attended the Italian everywhere for the space of a fortnight. The stranger now began to complain of want of money, which alarmed M. Gros not a little, for at that time he was very poor, and he became apprehensive, from the tenour of the stranger's conversation, that he intended to ask the loan of money from him. But instead of this, the Italian asked him if he was acquainted with any goldsmith, whose bellows and other utensils they might be permitted to use, and who would not refuse to supply them with the different articles requisite for a particular process which he wanted to perform. M. Gros named a M. Bureau, to whom the Italian immediately repaired. He readily furnished crucibles, pure tin, quicksilver, and the other things required by the Italian. The goldsmith left his workshop, that the Italian might be under the less restraint, leaving M. Gros, with one of his own workmen, as an attendant. The Italian put a quantity of tin into one crucible, and a quantity of quicksilver into another. The tin was melted in the fire, and the mercury heated. It was then poured into the melted tin, and at the same time a red powder enclosed in wax was projected into the amalgam. An agita-

* BRAY'S *Memoirs of John Evelyn*.

tion took place, and a great deal of smoke was exhaled from the crucible; but this speedily subsided, and the whole being poured out, formed six heavy ingots, having the colour of gold. The goldsmith was called in by the Italian, and requested to make a rigid examination of the smallest of these ingots. The goldsmith not content with the touchstone and the application of aquafortis, exposed the metal on the cupel with lead, and fused it with antimony, but it sustained no loss. He found it possessed of the ductility and specific gravity of gold; and full of admiration, he exclaimed that he had never worked before upon gold so perfectly pure. The Italian made him a present of the smallest ingot as a recompense, and then, accompanied by M. Gros, he repaired to the Mint, where he received from M. Bacuet, the mint-master, a quantity of Spanish gold coin, equal in weight to the ingots which he had brought. To M. Gros he made a present of twenty pieces, on account of the attention that he had paid to him; and, after paying his bill at the inn, he added fifteen pieces more, to serve to entertain M. Gros and M. Bureau for some days, and in the mean time he ordered a supper, that he might, on his return, have the pleasure of supping with these two gentlemen. He went out, but never returned, leaving behind him the greatest regret and admiration. It is needless to add, that M. Gros and M. Bureau continued to enjoy themselves at the inn till the fifteen pieces, which the stranger had left, were exhausted."

Many of the alchemists have given in detail the processes for the preparation of the Philosopher's Stone; but they are all unsatisfactory, and many of them unintelligible*. The following, which is one of the plainest, is offered as a sample of the general tenour of their proceedings; it is the formula of Carolus Musitanus†.

"1. Prepare a quantity of spirit of wine, so free from water that it is wholly combustible, and so volatile that when a drop of it is let fall it evaporates before it reaches the ground; this constitutes the first menstruum.

"2. Take pure mercury, revived in the usual manner from cinnabar; put it into a glass vessel with common salt and distilled vinegar; agitate violently, and when the vinegar acquires a black colour, pour it off and add new vinegar; agitate again, and continue these repeated agitations and additions till the vinegar ceases to acquire a black colour from the mercury: the mercury is now quite pure and very brilliant.

"3. Take of this mercury four parts; of sublimed mercury‡ (*mercurii meleorisati*), prepared with your own hands, eight parts; triturate them together in a wooden mortar with a wooden pestle, till all the grains of running mercury disappear. This process is tedious and rather difficult.

"4. The mixture thus prepared is to be put into an aludel, or a sand-bath, and exposed to a subliming heat, which is to be gradually raised till the whole sublimes. Collect the sublimed matter, put it again into the aludel, and sublime a second time; this process must be repeated five times. Thus a very sweet and crystallized sublimate is obtained: it constitutes the salt of wise men (*sal sapientum*), and possesses wonderful properties§.

* See STAHL's *Fundamenta Chemicæ*,
and JUNKER's *Conspectus Chemicæ*.

† MANGETI *Bibliotheca Chémica*.

‡ Probably corrosive sublimate.

§ Probably calomel.

"5. Grind it in a wooden mortar, and reduce it to powder; put it into a glass retort, and pour upon it the spirit of wine (No. 1) till it stands about three finger-breadths above the powder; seal the retort hermetically, and expose it to a very gentle heat for seventy-four hours, shaking it several times a-day; then distil with a gentle heat and the spirit of wine will pass over, together with spirit of mercury. Keep this liquid in a well-stopped bottle, lest it should evaporate. More spirit of wine is to be poured upon the residual salt, and after digestion it must be distilled off as before; and this process must be repeated till the whole salt is dissolved, and distilled over with the spirit of wine. You have now performed a great work. The mercury is now rendered in some measure volatile, and it will gradually become fit to receive the tincture of gold and silver. Now return thanks to God, who has hitherto crowned your wonderful work with success; nor is this great work involved in Cimmerian darkness, but clearer than the sun; though preceding writers have imposed upon us with parables, hieroglyphics, fables, and enigmas.

"6. Take this mercurial spirit, which contains our magical steel in its belly, put it into a glass retort, to which a receiver must be well and carefully luted: draw off the spirit by a very gentle heat, there will remain in the bottom of the retort the quintessence or soul of mercury; this is to be sublimed by applying a stronger heat to the retort that it may become volatile, as all the philosophers express themselves,

Si fixum solvas faciesque volare solutum,
Et volucrum figas faciet te vivere tutum.¹

This is our luna, our fountain, in which the king and queen may bathe. Preserve this precious quintessence of mercury, which is very volatile, in a well-shut vessel for further use.

"7. Let us now proceed to the operation of common gold, which we shall communicate clearly and distinctly, without digression or obscurity; that from vulgar gold we may obtain our philosophical gold, just as from common mercury we obtained, by the preceding processes, philosophical mercury.

"In the name of God, then, take common gold, purified in the usual way by antimony, convert it into small grains, which must be washed with salt and vinegar, till it be quite pure. Take one part of this gold, and pour on it three parts of the quintessence of mercury; as philosophers reckon from seven to ten, so we also reckon our number as philosophical, and we begin with three and one; let them be married together like husband and wife, to produce children of their own kind, and you will see the common gold sink and plainly dissolve. Now the marriage is consummated; now two things are converted into one: thus the philosophical sulphur is at hand, as the philosophers say, *the sulphur being dissolved, the stone is at hand*. Take then, in the name of God, our philosophical vessel, in which the king and queen embrace each other as in a bedchamber, and leave it till the water is converted into earth, then peace is concluded between the water and fire, then the elements have no longer anything contrary to each other; because, when the elements are converted into earth they no longer oppose each other; for in earth

all elements are at rest. For the philosophers say, 'When you shall have seen the water coagulate itself, think that your knowledge is true, and that your operations are truly philosophical.' The gold is now no longer common, but ours is philosophical, on account of our processes: at first exceedingly fixed, then exceedingly volatile, and finally exceedingly fixed; and the whole science depends upon the change of the elements. The gold at first was a metal, now it is a sulphur, capable of converting all metals into its own sulphur. Now our tincture is wholly converted into sulphur, which possesses the energy of curing all diseases: this is our universal medicine against all the most deplorable diseases of the human body; therefore, return infinite thanks to Almighty God for all the good things which he has bestowed upon us.

"In this great work of ours, two modes of fermenting and projecting are wanting, without which the uninitiated will not easily follow our process. The mode of fermenting is as follows:—Take of our sulphur above described one part, and project it upon three parts of very pure gold fused in a furnace; in a moment you will see the gold, by the force of the sulphur, converted into a red sulphur of an inferior quality to the first sulphur: take one part of this, and project it upon three parts of fused gold, the whole will be again converted into a sulphur, or a friable mass; mixing one part of this with three parts of gold, you will have a malleable and extensible metal. If you find it so, well; if not, add other sulphur, and it will again pass into sulphur. Now the sulphur will be sufficiently fermented, or our medicine will be brought into a metallic nature.

"The mode of projecting is this:—Take of the fermented sulphur one part, and project it upon ten parts of mercury, heated in a crucible, and you will have a perfect metal; if its colour is not sufficiently deep, fuse it again, and add more fermented sulphur, and thus it will acquire colour. If it becomes frangible, add a sufficient quantity of mercury and it will be perfect.

"Thus, friend, you have a description of the universal medicine, not only for curing diseases and prolonging life, but also for transmuting all metals into gold. Give therefore thanks to Almighty God, who, taking pity on human calamities, has at last revealed this inestimable treasure, and made it known for the common benefit of all."

Nearly all the alchemists attributed the power of prolonging life, either to the philosopher's stone, or to certain preparations of gold, imagining possibly that the permanence of that metal might be transferred to the human system. The celebrated DESCARTES is said to have supported such opinions; he told Sir KENELM DIGBY, that although he would not venture to promise immortality, he was certain that life might be lengthened to the period of that of the Patriarchs. His plan, however, seems to have been the very rational one of limiting all excess of diet, and enjoining punctual and frugal meals*.

The history of alchemy has been greatly enriched by the labours of the celebrated ELIAS ASHMOLE, who in 1652 published his *Theatrum Chemicum Britannicum*, containing several Poetical Pieces of our famous

* See *Life of Descartes*, CHALMERS'S *Biographical Dictionary*.

English Philosophers, who have written the Hermetique Mysteries in their owne ancient Language.

The most remarkable piece in this collection is the *Ordinall of Alchimy*, by THOMAS NORTON, illustrated by several curious cuts. It treats, in separate chapters, of the objects of the occult science; of the difficulties of attaining them; of the different methods of pursuing them; of the characters of the elements; and of the five concords, of which the first is *Patience*, the second *Assistance*, the third *Instruments*, the fourth *Situation*, and the fifth *Planetary Influence*. It is difficult to select from this production any specimen capable of conveying an idea of its merits, that can come within the limits of a quotation. Perhaps the following lines, picked out of the seventh chapter, touching "the Regiment of Fiers," may serve to convey some idea of the author's talents in the double capacity of poet and philosopher:—

In many authors written you may see,
Totum consistit in ignis regimine;
 Wherefore in all things so proceed,
 That heat work no more no less than it need;
 Wherein many of Geber's cooks
 Deceived were, though they be wise in books.
 Such heate wherewith a pig or goose is scalded
 In this arte *Decoction* it is called;
 Such heate as dryeth lawne karchiefs fair,
 In thirty operations serveth for our ayre!
 But for divisions you must use such heate,
 As cook's make when they roaste raw meate.
Ignis humidus another fier alsoe
 Is, and yet seemeth *oppositum in adjecto*:
 Another fier is fier of desication,
 For matters which be imbibed with humectation.
Ignis corrodens serveth in this arte,
Elementa propinqua wisely to depart.
 By one point of excess all your work is shent,
 And one point too little is insufficient;
 Who can be sure to find its true degree,
Magister magnus in igne shall he be.
 All that hath pleasure in this booke to reade,
 Pray for my soule, and all both quick and deade.
 In this year of Christ 1477,
 This work was began, honour to God in heaven.

In later times we have had two or three believers in transmutation. In the year 1782, Dr. PRICE of Guildford, by means of a white and red powder, professed to convert mercury into silver and gold, and is said to have convinced many disbelievers of the possibility of such change; his experiments were to have been repeated before an adequate tribunal, but he put a period to his existence by swallowing laurel-water.

Another true believer in the mysteries of this art was PETER WOULFE, of whom it is to be regretted that no biographical memoir has been preserved. I have picked up a few anecdotes respecting him from two or three friends who were his acquaintance. He occupied chambers in Barnard's Inn, while residing in London, and usually spent the summer in Paris. His rooms, which were extensive, were so filled with furnaces and apparatus that it was difficult to reach his fire-side. Dr. Babington told me, that he once put down his hat, and never could find it again, such was

the confusion of boxes, packages, and parcels, that lay about the chamber. His breakfast hour was four in the morning; a few of his select friends were occasionally invited to this repast, to whom a secret signal was given by which they gained entrance, knocking a certain number of times at the inner door of his apartment. He had long vainly searched for the elixir, and attributed his repeated failures to the want of due preparation by pious and charitable acts. I understand that some of his apparatus is still extant, upon which are supplications for success, and for the welfare of the adepts. Whenever he wished to break an acquaintance, or felt himself offended, he resented the supposed injury by sending a present to the offender, and never seeing him afterwards. These presents were sometimes of a curious description, and consisted usually of some expensive chemical product or preparation. He had an heroic remedy for illness: when he felt himself seriously indisposed, he took a place in the Edinburgh mail, and, having reached that city, immediately came back in the returning coach to London. A cold, taken on one of these expeditions, terminated in an inflammation of the lungs, of which he died in 1805. He is the author of several papers in the *Philosophical Transactions*. Several pieces of his apparatus, and, among others, an *athanor*, or self-supplying furnace, were given me by Mr. HATCHETT, who purchased them of Mr. Woulfe: they are in the Laboratory of the Royal Institution.

A few other persons of less note might be quoted as believers in transmutation, but the history of one is that of all; and, in the emphatic language of Spenser, they were doomed

To lose good days that might be better spent,
To waste long nights in pensive discontent;
To speed to-day, to be put back to-morrow,
To feed on hope, to pine with fear and sorrow;
To fret their souls with crosses and with cares,
To eat their hearts through comfortless despairs:
Unhappy wights! born to disastrous end,
That do their lives in tedious tendance spend.

But although the alchemists have given us little in the way of useful facts or applicable discoveries, their reign was fruitful in the invention of apparatus. Alembics, stills, retorts, receivers, and a variety of whimsical and complex vessels, in glass and porcelain, are described and depicted in their works; and they not only possessed nearly all the furnaces with which our modern laboratories are necessarily supplied, but were particularly expert in their construction.

§ III.

THERE are many points in alchemical history which have been purposely passed over, as affording nothing worthy of remark, and as suggesting nothing that throws light upon the brighter ages of chemistry. It has been too common to load the alchemists with honours which they ill deserve: the picture of their proceedings, already given, is as correct and faithful as the materials that compose it admit of, and it presents little that the mind rests upon with satisfaction, or reverts to with interest or profit. But there were contemporaries with the alchemists, whose pursuits were conducted upon more rational principles, and whose writings,

though often overshadowed by the clouds of magic and astrology, are, in many instances, illumined by rays of sober experimental investigation: they often indulge in the insane caprices of the mere searchers for the philosopher's stone, but their madness has method in it, and their wanderings are not without a plan.

Of these, the first I shall notice, is BASIL VALENTINE* of Erfurth, who wrote about the middle of the fifteenth century, and who may justly be considered as one of those whose labours contributed to the foundation of modern chemistry: his experiments always had an object, and he details them with intelligible perspicuity. It is true that he often launches into alchemy, but he returns unpolluted by its follies: where he speaks as an adept he is as absurd as need be; but, as the narrator of experiments, he abounds in shrewd remarks, and was uncommonly successful in his pursuits. The extant works of BASIL VALENTINE are not numerous, and they have mostly become scarce. In 1671 his *Triumphal Chariot of Antimony* was republished at Amsterdam, from the original edition of 1624, with copious notes by Dr. THEODORE KIRKCRINGIUS; and a few years after an English translation of that celebrated production was printed at London. In 1644 his *Haliographia* appeared at Bologna. This work treats of the preparation, uses, and virtues of mineral, animal, and vegetable salts, and is a curious and well-digested body of information upon a variety of chemical subjects. These are the only works of BASIL VALENTINE that I have been able to meet with, and I believe they contain the pith of his chemical knowledge. In both these works he appears in the double capacity of chemist and physician. In physic he was a brave champion for the chemical sect, and his *Triumphal Chariot of Antimony*, especially, abounds in reflections, not of the mildest description, upon the practice and theories of his adversaries, whom he despises, because, unable to prepare their own medicines, "they know not whether they be hot or cold; moist or dry; black or white; they only know them as written in their books, and seek after nothing but money. Labour is tedious to them, and they commit all to chance; they have no conscience; and coals are outlandish wares with them; they write long scrolls of prescriptions, and the apothecary thumps their medicine in his mortar, and health out of the patient."

But when we find many most important facts recorded in the pages of this writer, we shall readily excuse the irrelevant matter by which they are accompanied; and, in this view, his writings deserve the attentive perusal of those who would trace modern improvements to their parent inventions and discoveries, and these to their more remote and recondite sources. To say nothing of the important preparations of antimony with which BASIL VALENTINE enriched the *Materia Medica*, and of which he has given an intelligible and copious account in the *Currus Triumphalis*, we find in his works the first accurate directions for the preparation of nitric, hydrochloric, and sulphuric acids; and were these his only contributions to the laboratory, I need hardly say how richly he merits the eulogies of the moderns, when we reflect upon the numerous uses to which those acids are now applied, upon their importance in several of the most refined and extensive branches of art, and upon the ad-

* Born about the year 1400.

vances in technical and scientific chemistry which have been attained by their aid.

In order to obtain the *water of nitre*, for by that name he designates the acid, VALENTINE directs us to distil three parts of powdered earthenware with one of nitre. The mixture is to be subjected in a proper earthen alembic to a red heat, and a capacious receiver annexed. Now, this process is, in some places, still practised, and, although neither convenient, nor, generally speaking, economical, the acid it affords is sufficiently pure. The opinion of the old chemists, respecting this production of nitric acid, was, that the clay held down the nitre so as to expose it to the searching influence of the fire; but the decomposition depends upon the attraction of the potassa of the nitre for the ingredients of the clay, a kind of red slag remaining in the retort.

Another mode of procuring nitric acid mentioned by this writer, though probably of more ancient date, since RAYMOND LULLY seems to have known it, comes nearer to the process now in common use, and may, in many situations, be conveniently and economically practised. It consists in distilling equal parts of nitre and green vitriol. The residue consists of sulphate of potassa and oxide of iron; the former may be separated by washing with hot water, and an oxide of iron, of a deep red colour remains, used by the polishers of plate-glass, under the name of *colcothar*.

Under the directions for preparing the salt of gold in the *Haliographia*, I find a third mode suggested for the production of acid from nitre, which consists in distilling saltpetre with finely-pounded flints. It depends upon the attraction of silica for potassa, which combine to form a glassy slag, or silicate of potassa.

Such are the facts which are recorded by BASIL VALENTINE respecting the preparation of nitric acid; he termed it *water*, or *acid spirit* of nitre. It was afterwards called *aquafortis*; and its property of dissolving gold, with the addition of sal ammoniac, or of hydrochloric acid, is often adverted to and descanted upon by the same author.

For nearly two hundred years after the discovery of *aquafortis*, its chemical history was but little advanced; nor, indeed, were any facts of importance respecting its true nature made out, until Dr. PRIESTLEY and Mr. CAVENDISH commenced their researches, about the middle of the last century.

But the discovery of nitric acid is certainly second in importance to that of oil of vitriol, or, as it is now called, *sulphuric acid*, the honour of which is also due to BASIL VALENTINE; for it is not, as far as my information goes, described in any earlier writer: he frequently mentions it, and the mode of its preparation; and PARACELUSUS, and the authors who immediately followed, talk of it as well known, and in common use, though it is probable that it bore a higher price, and was but scantily supplied.

In the *Currus Triumphalis*, the spirit afforded by the distillation of vitriol is not unfrequently adverted to, and its action upon certain antimonial compounds so fully described, as to leave no doubt respecting its nature. In the *Haliographia*, however, *oil of vitriol* is distinctly mentioned; and, what is curious, we find in the chapter of that tract relating to the extraction of the salts of iron, particular directions for the prepara-

tion of sulphate of iron, by dissolving iron filings in a mixture of one part of oil of vitriol and two of water: this solution, he says, "when put aside in a cool place, soon forms beautiful crystals;" and in another section we are told, that "this salt is an excellent tonic; that it comforts weak stomachs; and that, externally applied, it is an admirable styptic." And this, in fact, is nearly all that we can say of the preparation and medical uses of this salt of iron at the present day.

The mode of obtaining sulphuric acid, by the distillation of sulphate of iron, or green vitriol, is still extensively practised upon the Continent, in Germany, Sweden, and more especially at Bleyl, in Bohemia*. The vitriol is first deprived of water of crystallization, and then submitted, in glass retorts coated with clay, to a red heat; white fumes pass over into the receivers, which become very hot during the condensation of these fumes into an unctuous reddish-brown fluid, which, from its viscosity and appearance, acquired the name of *oil of vitriol*: there remains in the vessels a substance of a fine red colour, which, when washed and levigated, furnishes the *colcothar*, or *caput mortuum* of vitriol; for the old chemists were in the habit of representing the dregs and last products of substances by the symbol of a death's head and cross-bones.

The oil of vitriol, thus prepared, exhales fumes when exposed to a moist atmosphere, and occasionally congeals or crystallizes; circumstances which led to its name of *glacial oil of vitriol*, and which show that it differs from the acid as ordinarily prepared. It contains, in fact, the anhydrous acid.

That sulphur, during combustion, produces a portion of acid matter, seems to have been known at a very early period; the method of obtaining sulphuric acid by burning a mixture of sulphur and nitre is described by VALENTINE in his *Chariot of Antimony*, under the name of *oil of antimony*, for he employed sulphuret of antimony, as well as sulphur, in its production. The original recipe runs thus:—

"Take of antimony, sulphur, salt nitre, of each equal parts, fulminate them under a bell, as oil of sulphur, *per campanam*, is made, which way of preparing hath long since been known to the ancients; but you will have a better way if instead of a bell you take an alembic, and apply to it a recipient; so you will obtain more oil, which will indeed be of the same colour as that made of common sulphur, but in powers and virtues not a little more excellent."

Dr. WARD, the inventor of many celebrated nostrums, was the first person who brought this mode of preparing sulphuric acid into notice in England; he obtained a patent for his invention, and for a considerable time monopolized the manufacture. At length Dr. ROEBUCK, an eminent physician of Birmingham, substituted an apparatus of lead for the glass vessels previously used. This was in 1746, since which the price of sulphuric acid has been greatly reduced, and the manufacturer consequently enabled to employ it for a variety of purposes, to which it was previously inapplicable, from its scarcity and high price. In 1772, the first manufactory of sulphuric acid near the metropolis was established by Messrs. KINGSCOTE and WALKER, at Battersea†.

* AIKIN'S *Dictionary*, art. Sulphuric Acid. † PARKES' *Chemical Essays*, vol. ii., p. 388.

I have mentioned that the necessity and advantages of nitre, as an addition to sulphur in increasing the acid product, was known to VALENTINE; but the manner in which it operates is a later discovery. As the expense of the operation is increased by it, many attempts have been made to supersede its use, by the employment of other materials, under the impression that it merely furnished oxygen; but a little reflection easily proves the fallacy of such a notion; for, even if we burn sulphur in pure oxygen, sulphurous, and not sulphuric acid, is the result. The solution of this chemical problem has been chiefly effected by the researches of M.M. CLEMENT and DESORMES, and Sir H. DAVY, who have proved that the products of the nitre are concerned in transferring oxygen to the sulphur. A patent has more lately been taken out for a mode of preparing sulphuric acid by the combustion of pyrites, without the intervention of nitre, but its success is doubtful.

The numerous antimonial preparations described in the *Chariot of Antimony* deserve more notice than they have generally received from the chemical historian; and the perusal of that work affords some insight into the celebrated disputes between the galenical and chemical physicians, which were afterwards pushed so far by PARACELSUS.

BASIL VALENTINE, adverting to the notion that antimony* was poisonous, tells us, that its noxious qualities may not only be subdued by art, but that various properties may be communicated to its different preparations—"As a blacksmith," he says, "with one sort of fire, and iron only is his matter, of which he forms divers instruments. Sometimes he makes a spit, at another time horse-shoes, another time a saw, and at length innumerable other things, every of which serves for that use for which the smith intended it. So of antimony various works may be made for different uses; in which the artist is the smith that forms, Vulcan is the key which opens, and operation and utility give experience and knowledge of the use. Oh, if foolish and vain men would hear and understand what I write, they would not suck their turbid and insalubrious potions, but hasten to these limpid fountains, and drink of the well of life."

In pursuing his defence of antimony, the author allows its venomous nature, but then tells us, that upon that circumstance its value in medicine depends, upon the principle that venom draws venom to itself; and adduces, as proof of this position, the well-known fact, as he terms it, that a dried toad reduced to powder, and sprinkled upon the wound occasioned by a viper's bite, cures it.

§ IV.

PARACELSUS comes next in chronological order to his predecessor, BASIL VALENTINE, but as a chemist he falls far short of that master; his original

* It is probable that the word *Antimony* was first used by Basil Valentine. Tradition relates that having thrown some of it to the hogs, after it had purged them heartily, they immediately fattened; and, therefore, he imagined

that his fellow monks would be the better for a like dose, they having become lean by fasting and mortification. The experiment, however, failed, and they died; whence the medicine was called *Antimoine*.

discoveries are few and unimportant, and his great merit lies in the boldness and assiduity which he displayed in introducing chemical preparations into the *Materia Medica*, and in subduing the prejudices of the galenical physicians against the productions of the laboratory. The principal events of his life are the following: His real name was PHILIP HOCHENER, which he changed, on commencing his professional career, into THEOPHRASTUS BOMBASTUS PARACELUS*. At an early age he visited the most renowned towns in Europe, and, returning to his native country, was made Professor of Medicine and Chemistry at Basle; he availed himself of this public situation, not to instruct the unlearned, but to vilify his contemporaries and predecessors. It is generally said, that his dissolute manners and intractable temper obliged him to quit his occupation. But others have told a more plausible story: a rich Canon fell sick, and getting frightened, offered a hundred florins to any one who would cure him. PARACELUS administered three pills, and the Canon got well; but being so soon restored, and by such simple means, he refused to fulfil his promise. The matter was brought before a magistrate, who decreed that the doctor should only recover the customary fee. Irritated at the flimsy excuses and unpardonable ingratitude of the priest, and at the magistrate's partial decision, PARACELUS declared that he would leave the inhabitants of Basle to the eternal destruction which they deserved: he then retired to Strasburgh, and thence into Hungary, where he took to drinking, and died in great poverty at Salzburgh, in 1541, and in the forty-third year of his age. Though we can fix upon no particular discovery on which to found his merits as a chemist, and though his writings are deficient in the acumen and knowledge displayed by several of his contemporaries and immediate successors, especially by THEODORE DE MAYERNE, and DU CHESNE, or, as he was generally called, QUERCITANUS†, it is undeniable that he gave a most important turn to pharmaceutical chemistry; and calomel, first described by CROLLIUS‡ in 1609, with a variety of mercurial and antimonial preparations, as likewise opium, came into general use. Although the chemical physicians, however, were very successful, they were aware of the unpopularity of their means; people were frightened at the idea of mercury and antimony,

* "Hunc virum," says Boerhaave, "alii coluerunt pro Deo, imo locutus sum cum hominibus qui credunt eum non esse mortuum, sed vivum sedere in sepulchro pertæsum peccatorum et malorum hominum." The following is an illustrative anecdote of his impudence: "Cum adscenderet Cathedram physico-medicam, sumsit vas æneum cum igne, immisit sulphur et nitrum, et simul Galenum, Avicennam, et Arabes conjecit in ignem, dicens, sic vos ardebitis in gehennâ."

† Du Chesne was a native of Gascony, and physician to Henry the Fourth.

‡ Oswald Crollius was physician to the Prince of Anhalt, and a counsellor of the Emperor Rodolph the Second. His practice and system were opposed

by the celebrated Andrew Libavius, of Halle, who died in 1616. His works were published in 1615, at Frankfort, in 3 vols., folio. Libavius was succeeded by Angelus Sala, of Vicenza, physician to the Duke of Mecklenburgh Schwerin, whose works were published at Frankfort, in 1647, in 1 vol., 4to. The perusal of these authors will be interesting to those who are studying the history of medicine, on account of the important additions which they made to Chemical Pharmacy, and the new substances with which they enriched the *Materia Medica*. They were followers of the doctrines of Paracelsus, but divested their practice of the absurdities in which his tenets were involved.

which were accordingly exhibited under fantastic and assumed names. Towards the end of the fifteenth century, the use of antimony was prohibited at Paris; and BESNIER was expelled the faculty for having persevered in administering it. In England, chemical medicines first began to be extensively employed in the reign of Charles the First. In 1644 SCHRÖDER published his *Chemico-Medical Pharmacopœia*; and shortly after, that of the London College made its appearance; but although the history of pharmaceutical chemistry must not be blended with the abstract progress of the science, yet should it not be forgotten, that the great modern improvements in chemistry have sprung from its applications to medicine, and that the foundations of chemical science are to be found in the medical and pharmaceutical writers of the sixteenth century, who rescued it from the hands of the alchemical pretenders, and gave it a place and character of its own.

The enthusiastic ravings of PARACELSUS tended to awaken the more solid talents of VAN HELMONT of Brussels, who flourished in the early part of the seventeenth century, and who studied and admired the works of his less modest predecessor. VAN HELMONT has left a curious memoir, containing a sketch of his own life, and exhibiting the various circumstances that gave an impulse to his proceedings, and the different causes that suggested his pursuits. In this biographical relic, there is a vein of sound and unaffected argument, which displays a very amiable turn of mind in the writer. It would, however, be irrelevant to my present subject to give more than a brief abstract, illustrative of the style and pursuits of the author:—"In 1594, being then seventeen years of age, I finished my course of philosophy; but upon seeing none admitted to examinations at Louvain who were not in a gown and hood, as though the garment made the man, I was struck with the mockery of taking degrees in arts. I therefore thought it more profitable seriously and conscientiously to examine myself; and then I perceived that I really knew nothing, or, at least, nothing that was worth knowing. I had, in fact, merely learned to talk and to wrangle, and therefore refused the title of Master of Arts, finding that nothing was sound, nothing true, and unwilling to be declared master of the seven arts, when my conscience told me I knew not one. The Jesuits, who then taught philosophy at Louvain, expounded to me the disquisitions and secrets of magic; but these were empty and unprofitable conceits; and, instead of grain, I reaped stubble. In moral philosophy, when I expected to grasp the quintessence of truth, the empty and swollen bubble snapped in my hands. I then turned my thoughts to medicine, and having seriously read GALEN and HIPPOCRATES, noted all that seemed certain and incontrovertible; but was dismayed upon revising my notes, when I found that the pains I had bestowed, and the years I had spent, were altogether fruitless; but I learned at least the emptiness of books and formal discourses and promises of the schools. I went abroad, and there I found the same sluggishness in study, the same blind obedience to the doctrines of their forefathers, the same deep-rooted ignorance*."

* *Johannis Baptistæ Van Helmont* | extract is from the *Studia Authoris*,
Opera omnia. Hafn. 1707. The above | p. 16.

VAN HELMONT was called by his contemporaries an insane enthusiast; but there is, even in the imperfectly translated and brief quotation which I have taken from the history of his studies, a propitious gleam of that dawn of improvement which was diffused over science by the genius of Lord BACON.

The doctrine of the Chemical Elements was in full vogue during the time of VAN HELMONT, PARACELSUS, and VALENTINE, and salt, sulphur, and mercury, are unequivocally mentioned as the ultimate component parts of almost all the forms of matter. In the writings of VAN HELMONT, there are sundry allusions to the existence of æriform bodies, and the word *gas*; now in common use, and applied to all æriform matters differing from atmospheric air, first occurs in his pages: he also distinguishes between condensable gases or vapours, and incondensable or permanently elastic fluids; and under the term *gas silvestre*, he seems to comprehend what was afterwards called *fixed air*. As to the general tenour of his writings, it is difficult to separate the chemistry from the miscellaneous matters, and more especially from the medical commentaries with which it is blended; but they abound in hints and observations, which are ingenious and acute. In his experiments on air, he argued very plausibly on its weight and elasticity; and has detailed with much precision the effect of temperature and pressure, in his description of the air thermometer.

Entering upon the seventeenth century, the historian of Experimental Science must ever pause to pay a tribute of gratitude and respect to the celebrated FRANCIS BACON; a man whose faults as a statesman have been eclipsed to the eyes of posterity by the brilliancy and excellence of his philosophical character.

It may usually be observed, that those who are gifted by nature with superior genius or uncommon capacity, who are destined to reach the meridian of science, or to attain exalted stations in the learned professions, have exhibited early symptoms of future greatness: either indefatigable industry, or extraordinary sagacity, or ardent enthusiasm, have marked their entrance into the affairs of life. At the age of sixteen, BACON was distinguished at Cambridge; and, very shortly afterwards, struck with the frivolous subtilty of the tenets of ARISTOTLE, he appears to have turned his mind into that channel which led on to future eminence. The solid foundation of his scientific character is the *Instauration of the Sciences*. It opens with a general and philosophical survey of the subject; whence he proceeds to infer the futility of the ancient philosophical systems, and to point out Induction, from sober and severe experiment, as the only road to truth. Pursue this, he says, and we shall obtain new powers over nature; we shall perform works as much greater than were supposed practicable by natural magic, as the real actions of a Cæsar surpass the fictitious ones of a hero of romance. Speculative Philosophy he likens to the lark, who brings no returns from his elevated flight; Experimental Philosophy to the falcon, who soars as high, and returns the possessor of his prey. Illustrations of the new method of philosophizing, and the mode of arranging results, conclude this admirable and unrivalled performance.

To do justice to this work, we must, for a moment, forget the present

healthy and vigorous constitution of science, and view it deformed and sickly in the reign of ELIZABETH. We shall then not be surprised at the irrelative observations and credulous details which occasionally blemish this masterly production of the human mind.

But the history of LORD BACON furnishes other materials for reflection. Upon the accession of JAMES THE FIRST, he became successively possessed of the highest honours of the law, and acquired great celebrity as a public speaker and a man of business; yet, amidst the harassing duties of his laborious avocations, he still found time to cultivate and adorn the paths of science, the pursuit of which furnished employment for his scanty leisure and relaxation in his professional toils; and, when ultimately disgraced, "his genius, yet unbroken, supported itself amidst involved circumstances and a depressed spirit, and shone out in literary productions." Nor should the munificence of his royal master remain unmentioned, who, after remitting his fine, and releasing him from his prison in the Tower, conferred upon him a large pension, and used every expedient to alleviate the burden of his age, and to blunt the poignancy of his sufferings.

After the death of LORD BACON, which happened in April, 1626, in the sixty-sixth year of his age, the records of science begin to assume a brighter aspect; and we discern true knowledge emerging from the dungeons of scholastic controversy, and shaking off the chains of polemical learning.

The middle of the seventeenth century was a period extremely fertile in chemical productions. In taking, however, a comprehensive view of the writers of this age, there are a few only whose labours deserve to be recorded as connected with the advancement of chemical knowledge; that is, as having contributed, by new views and discoveries, to the progress of what may be termed the philosophy of the science. They were generally mere recorders of insulated facts, or publishers of ill-digested and imperfectly-arranged catalogues of the various preparations that were used in the arts and in medicine; for the dread in which chemical preparations were viewed by physicians began now to decline; the *Materia Medica* was filled with new and more convenient forms, and the *Pharmacopœiæ*, published under the authority of different governments, were allowed to divulge the preparation of calomel, emetic tartar, and several other important and useful compounds.

Among the writers of this period there is no one more rich in facts, and original in invention, than GLAUBER of Amsterdam. KUNCKEL was a successful promoter of chemistry applied to the arts: he wrote on the production of phosphorus, and on the art of glass-making, and was a favourite at many courts of Europe, more especially with CHARLES THE ELEVENTH of Sweden, who, in 1693, granted him letters of nobility. In 1673, LEMERY, the elder, conferred much service on chemistry by his dexterity as an experimentalist, and by the plain, perspicuous style in which he publicly taught the rudiments of the science. The discovery of phosphorus belongs also to this period; and, although of little interest perhaps in the abstract, it drew a host of inquirers into the precincts of the laboratory, and was productive of more extensive and important consequences than have generally been attributed to it.

Of these writers, there is no one so deserving attention as GLAUBER: he was not a mere maker of experiments, but he reasoned sensibly and even acutely upon their results; he occasionally oversteps the bounds of modest argument, rudely deprecates the views of his contemporaries, and praises himself beyond all measure; but this vitiated style was then in fashion, and, unlike most of his contemporaries, he has very sufficient claims to originality of invention. His works were translated into English, and published, as the title runs, "for public good, by the labour, care, and charge of CHRISTOPHER PACKE, *Phylo-Chemico-Medicus*, in 1689."

GLAUBER was so laborious an experimentalist, and in his experiments there is so much originality, that it is difficult to select those which can strictly be called discoveries, and upon which his scientific character deserves chiefly to be founded.

The distillation of volatile alkali from bones, and its conversion into sal ammoniac by the affusion of spirit of salt; the preparation of sulphate of ammonia, which he calls *secret sal ammoniac*, and its conversion into common sal ammoniac by distillation with common salt; the production of blue vitriol by the action of acid of vitriol upon the green rust of copper; the distillation of vinegar from wood, and the formation of a variety of salts useful in medicine and the arts by its action upon alkaline, earthy, and metallic substances; the distillation of muriatic acid, or spirit of salt, from a mixture of common salt and acid of vitriol; and the extraction of sulphate of soda, or *sal mirabile*, from the residue of this experiment, are a few, and only a very few, of the truly important inventions and discoveries that crowd upon us in the perusal of the verbose pages of GLAUBER. Of these the production of vinegar of wood, and of muriatic acid, may perhaps be regarded as of the greatest interest. The acid liquor produced during the destructive distillation of wood has lately become a manufacture of much importance.

GLAUBER describes the distillatory apparatus, which he calls "a press for extracting the juice of wood;" he shows its condensation into an acid liquor; and directs the method of burning lime, by ranging layers of chalk alternately with those of the wood. He also says, that by rectifying the spirit of wood, "a sharp hot oil, of a dark reddish colour remains, and the *vinegar* passes over, fit for the preparation of medicines, and all other uses to which common vinegar is applicable." The oil, he adds, is an admirable preservative of wood, and when saponified with alkali, forms a most valuable manure; "a hogshead of which may be carried into fields and vineyards far remote, more easily than ten loads of common manure, which is carried to vineyards in rocky places with great difficulty. As to the spirit, physicians may use this noble and efficacious juice with great honour and profit in the cure of many diseases hitherto incurable;" and he highly extols the effects of a warm bath, acidulated by the vinegar of wood: he also shows the mode of concentrating it by exposure to cold, when "the phlegm only freezeth, but the sharp spirit remaineth in the middle of the hogshead, so sharp that it corrodeth metals like aqua fortis." After many other shrewd and clever remarks respecting the tar of wood and its acid, GLAUBER closes his discourse, fearing that it will not be believed by many, which, he says, he cannot help; "it contenteth me that I have written the truth, and lighted a candle to my neighbours."

The preparation of muriatic acid, as now commonly conducted, was first devised by GLAUBER; he obtained it by distilling common salt with acid of vitriol, and gives a sufficiently clear account of the nature of the chemical change that ensues. The residue of this operation retains to this day the name of *Glauber's salt*; or, as he termed it, *sal mirabile*. Upon its virtues he has descanted at great length, and though, in his history of this salt, its value and uses are preposterously exaggerated, his observations serve to show the diligence and acuteness with which he investigated its applications, and offer proofs of the extensive information which he possessed relative to many processes of agriculture and the arts. Salt, in short, was GLAUBER's favourite element: "It is," says he, "the beginning and the end of all things, and it increaseth and exalteth their powers and virtues: it is the true universal medicine; not that I would have any man persuade himself, that in these words I would assert immortality, for my purpose tendeth not thither, seeing that I am not ignorant there is no medicine against death." And then, adverting to the opposition to chemical medicines by contemporary physicians, he advises them not to envy those "who have received such divine gifts as his wonderful salt, nor to provoke the innocent with their filthy calumnies and slanders, but to leave those things which exceed their capacities. Nothing," he says, "can extinguish truth; it may be prest, but cannot be overcome; like the sun's light, it may be hidden, but not extinguished."

The directions he gives for the preparation of the *sal mirabile*, and the account of its properties, are in general very correct. "Its colour ought to be white and transparent: its figure is in long striæ or crystals: its taste is like ice melting upon the tongue, and yields some bitterishness. Being dried in the fire, and all the moisture gone off, it will lose about three parts of its own body, and retain a fourth part only; being dissolved in water, it will recover those three parts again. But, on the contrary, if it shoot into a square figure, and hath as yet a saltish taste, and being dried, loseth but little of its weight, it is not worth a rush, and shows that either the oil of vitriol was not good, or not enough of it used in the operation. These things we would not bury in silence, that so we might well advise young beginners, and withdraw them from their errors."

GLAUBER has great merit as an inventor and improver of chemical apparatus, much of which is depicted in the plates attached to his works. The form of distillatory vessels commonly called Woulfe's apparatus, is found in GLAUBER's *Chemical Furnaces*; and he contrived a very ingenious mode of heating large vessels of water by steam, and with great economy of fuel, a method now often resorted to.

He published a pamphlet, entitled *The Consolation of Navigators, in which is taught how they who travel by Sea may preserve themselves from Hunger and Thirst; and also from those Diseases which are wont to happen in long Voyages. Written for the Health, Comfort, and Solace of all those who travel by Water for the good of their Country*. The sensible plan of employing extract of malt as a portable vegetable diet, and dilute muriatic acid to quench thirst, is here recommended; and many of the medicinal uses of the muriatic acid are dwelt upon at length, which have been claimed as recent discoveries. On the whole, there is no author contemporary with GLAUBER, who has written so much to the

purpose, and in whom we find such abundant anticipations of modern scientific improvements. He was cast in the true mould of an experimental chemist, and had he lived in a more propitious age, would probably have rivalled SCHEELE and PRIESTLEY.

§ V.

It is now time to advert to the early proceedings of the Royal Society, as connected with the present subject, a body incorporated by CHARLES THE SECOND in 1662, under a Royal Charter, for the improvement of natural knowledge. The period of the foundation of this Society was peculiarly favourable to its interests and objects; the country, long distracted by the worst of all evils, a civil war, and afterwards oppressed by the military usurpation of CROMWELL, was threatened, upon the death of the Protector, with the horrors of anarchy, when the restoration of CHARLES THE SECOND healed all divisions, and checked the tide of revolutionary violence. Then was a propitious time to lead the rich and well-informed into the avenues of scientific inquiry, and to substitute the advancement of knowledge for political speculation. Among the first members of the Royal Society are the names of many who were eminent in mathematical and physical knowledge, and of more who afterwards became so: they were vehement in favour of experimental science, which was then in its infancy, and soon acquired vigour by their support; and it is curious to observe among the most active and zealous promoters of these peaceful studies, many who had been famed as party leaders, or actively engaged in political intrigues and revolutionary broils.

The early volumes of the *Philosophical Transactions*, of which the first bears date 1665, consist of small numbers, which were published at irregular intervals, and, from their miscellaneous contents, may be compared to the scientific journals of these days. Exclusive of papers read before the Royal Society, they contain many scraps of literary and scientific value collected by the secretary, Mr. OLDENBURGH. The publication was continued by Drs. GREW and HOOKE, but the latter discontinued it, probably from the sparing sale; and in 1683 we find Dr. PLOT resuming the editorship, upon condition that the members would bind themselves to purchase sixty copies of each number. The *Transactions* were periodically published, with some intermissions, however, by the Secretaries of the Society, till the year 1750, when the publication was put into the hands of a Committee of Papers; and since the year 1762 a volume has annually made its appearance*.

In 1666, the Royal Academy of Sciences was instituted at Paris, under the protection of LOUIS THE FOURTEENTH: in its annals the names of HOMBERG, GEOFFROY, and the two LEMERYS, soon became celebrated for their various discoveries and improvements in chemistry. HOMBERG†, under the auspices of the Regent Duke of ORLEANS, was an active and successful experimentalist. He discovered the boracic acid, which he prepared under the name of *sedative salt*. He was also the discoverer of *Pyrophorus*. GEOFFROY deserves mention as an active and scientific con-

* THOMSON'S *History of the Royal Society*.

† Born at Batavia, in Java, 1652; died at Paris, 1715.

tributor to pharmaceutical chemistry; he was also, I believe, the first compiler of the *Paris Pharmacopæia*.

The early proceedings of the Royal Society of London present many traits of the infant state of experimental science, and not a few absurdities might be selected from among them, the principal of which were lampooned by Sir JOHN HILL, in his *Review of the Works of the Royal Society of London*. This period, however, was adorned with the names of BOYLE* and of HOOKE†; the former a voluminous writer, of a most amiable temper and upright mind; the latter, an original and acute experimentalist, but a peevish and distrustful man‡.

Although BOYLE cannot be said to have fathomed the depths of science, yet his station in life, his mild and prepossessing disposition, his strict honour and integrity, and the unaffected earnestness with which he promoted experimental inquiry, tended to shed a lustre on his pursuits, to elevate their character with the world, and to draw into their precincts many who, without such an example, would have passed their lives in that listless inactivity, then too common with those upon whom fortune smiled; among them Mr. BOYLE made many converts. "It must be confessed," says his contemporary EVELYN, "that he had a marvellous sagacity in finding out many useful and noble experiments. Never did stubborn matter come under his inquisition, but he extorted a confession of all that lay in her most intricate recesses, and what he discovered he has faithfully registered and frankly communicated. In this," says EVELYN, "exceeding my Lord VERULAM, who (though never to be mentioned without honour and admiration) was used to tell all that came to hand. His severer studies did not in the least sour his conversation, and I question whether any man has produced more experiments without dogmatising. He was a corpuscularian without Epicurus; a great and happy analyser, addicted to no particular sect, but, as became a generous and free philosopher, preferring truth above all; in a word, a person of that singular candour and worth, that to draw a just character of him, one must run through all the virtues, as well as through all the sciences§."

* Boyle was born in January, 1627, at Lismore, in the Province of Munster, in Ireland. He was educated at Eton, and afterwards travelled in Italy, Switzerland, and France, and returned to England in 1644. In 1668 he took up his residence in London; and in 1680 was elected President of the Royal Society. He died on the 30th of December, 1691, aged sixty-four.

† Born in the Isle of Wight, 1635; died in London, 1702.

‡ Sir Godfrey Copley, in a letter written about the time of Hooke's death, says, "Dr. Hooke is very crazy; much concerned for fear he should outlive his estate. He hath starved one old woman already, and, I believe, he will endanger himself to save sixpence for anything he wants." In another, written a few weeks after his death, Sir Godfrey

says, "I wonder old Dr. Hooke did not choose rather to leave his 12,000*l.* to continue what he had promoted and studied all the days of his life, I mean mathematical experiments, than to have it go to those whom he never saw nor cared for. It is rare that virtuosos die rich, and it is a pity they should, if they were like him." Dr. DUCARREL'S MSS. quoted in *Biog. Dict.* Hooke sometimes declared that he intended to dispose of his estate for the advancement of natural knowledge, and to promote the ends for which the Royal Society was instituted; to build a handsome edifice for the Society's use, with a library, laboratory, and repository, and to endow a professorship. *Life by WALLER.*

§ BRAY'S *Memoirs of Evelyn*, 2nd edit. 4to., vol. ii., p. 268.

BOYLE died in December, 1691, and his funeral sermon was preached by the celebrated Dr. BURNET, at St. Martin's Church, "in which," says EVELYN, "he spake of his wonderful civility to strangers, the great good which he did by his experience in medicine and chemistry, the works, both pious and useful, which he published, the exact life he led, and the happy end he made*."

Upon the whole it may truly be said of BOYLE, that, though he enlightened and adorned the avenues of science, he scarcely enriched it; he wrote much, and generally to the purpose, but he is rather the historian than the actor. It may be remarked however, that in BOYLE, and especially in his contemporary, HOOKE, we have the first genuine samples of the influence of Lord BACON's doctrines, which actuated all their proceedings, and produced effects marvellously beneficial. Mr. BOYLE's Essays on the successfulness and unsuccessfulness of experiments, and the preface to his philosophical writings, are in the genuine spirit of experimental research; and HOOKE, in the preface to the *Micrographia*, has spoken so much to the point, and in language so novel and bold in the then state of science, that, upon perusing it, we are struck with the entire confidence which it bespeaks for his subsequent experimental details.

After adverting to the deep-rooted errors that have been grafted upon science, by the slipperiness of the memory, the rashness of the understanding, and the narrowness of the senses, and showing that these failings may, in some degree, be obviated by the right ordering and rendering them duly subservient to each other, he proceeds to point out the means of tracing the footsteps of nature, "not," as he says, "in her ordinary course only, but also in her doublings and turnings; and in this investigation, upon which the desirable reform in philosophy is to be founded, there is not so much required any strength of imagination, or exactness of method, or depth of contemplation, as a sincere hand and faithful eye, to examine and to record the things themselves as they really appear."

HOOKE then goes on to lament that "the science of nature has been too long made the work of the brain and of the fancy; let it now revert," says he, "to plain and sound observation; and let all intelligence be severely examined; let there be rigour in admitting, strictness in comparing, slowness in debating, and shyness in determining. The understanding is to order all the inferior services of the lower faculties; but yet it is to do this as a lawful master, and not as a tyrant. It must not encroach upon their offices, nor take upon itself the employments which belong to either of them. It must watch the irregularity of the senses, but not go before them, or prevent their information; it must examine, range, and dispose of the bank which is laid up in the memory; but it must be sure to make distinction between the sober and well-collected heap, and the extravagant ideas and mistaken images which there it may sometimes light upon." This is, indeed, the language of Lord BACON, by one who acted as he wrote, for HOOKE was a most diligent experimenter, and has recorded his results with all that cautious sobriety which he advises. "If ever," he says, "I have ventured at small conjectures respecting the causes of the things I have observed, I beseech the reader to

* BRAY's *Memoirs of Evelyn*, *Diary*, vol. ii., p 39.

look upon them only as doubtful problems and uncertain guesses, not as unquestionable conclusions, or matters of unconfutable science."

Among the new views and discoveries of HOOKE, connected with chemistry, and many of which are scattered through the writings of BOYLE, there are none of more importance than those relating to the phenomena of combustion, and to the part which the air performs in that process; and as we are now approaching an epoch of our history at which the appearances presented by burning bodies, and the changes which they undergo, were attentively examined and assiduously inquired into, and in which they were considered as one of the main objects of chemical research, it is right that we distinctly understand HOOKE's notions upon this subject, which will be found wonderfully acute, and remarkable for their boldness, as differing from theories then received; and for correctness as superseding the objections to which the other views are liable.

From the obscure hints in the writings of the alchymists, and from the more decided language of BASIL VALENTINE, PARACELSUS, and other writers of that cast, it appears that the phenomena of combustion were generally referred to the existence of some subtle and highly volatile principle, which, expanded and agitated by heat, produced flame and fire. When metals were exposed to the action of heat, the greater number were observed to alter their appearance, and, losing metallic brilliancy, became converted into an earth-like residue, to which the name of *Calx* was given. It was generally admitted that, in this process, the particles of the combustible were thrown into violent vibrations, and so transformed into heat and light; and such a supposition was natural enough, for it appears to a superficial observer, unacquainted with the results of modern discovery, that the matter burned is in a great number of cases entirely consumed, and that the principal products are light and heat.

A tract, extremely remarkable for the period at which it was written, appeared on this subject in France about, or previous to, the year 1630, relating to the increase of weight sustained by tin and lead during their calcination. LE BRUN having melted two pounds six ounces of tin, found that in six hours the whole had passed into the state of calx, weighing three pounds one ounce; and, being puzzled at the circumstance, he consulted REY, a physician of Perigord, as to its cause, who immediately set about an investigation of the matter, which terminated in explicitly referring the cause of the increase to the fixation of air*.

HOOKE in his investigations, and BOYLE by his experiments with the air-pump, which was now just perfected and coming into use, succeeded not merely in demonstrating the important part performed by the presence of atmospheric air in combustion, but HOOKE carried his inquiries still further, and, in his mind's eye at least, seems to have seen and anticipated the results that were gained at a much later period of chemical science, and established upon less questionable authority.

BOYLE found that a candle, charcoal, sulphur, and some other combustibles, would not burn in the exhausted receiver of his air-pump, which however produced a very imperfect vacuum. When he had pro-

* *Essays de JEAN REY, Docteur en Médecine, sur la Recherche de la Cause pour laquelle l'Estain et le Plomb, augmentent de poids quand on les calcine. Paris, 1717.*

cured a good vacuum, he found that gunpowder would not inflame in it by collision of flint and steel, which he properly attributed to the want of due heat in the sparks resulting from collision; for, on heating the powder in the focus of a lens, it exploded: hence he thought the nitre contained in the gunpowder was concerned in furnishing materials to supply the place of the air*.

HOOKE, in the sixteenth section of the *Micrographia*, relating to charcoal and burned vegetables, observes, that in the ordinary process for making charcoal, the consumption of the wood is prevented by the exclusion of air. The charcoal glows, it is true, but does not burn;—hence, he says, may we learn, that the air is the universal dissolvent of inflammable bodies,—that this dissolution generates heat, which we call fire, as is the case in many other dissolutions,—that this dissolution is made by a substance mixed with the air that is like unto, or the *very same*, as that which is fixed in saltpetre,—that, of the burning body, one portion is turned into air, and another portion is indissoluble,—that the dissolving parts of the air are but few, and hence the atmosphere is like those spirits that have much phlegm mixed with them, and become soon glutted; whereas saltpetre abounds more in those solvent particles, and hence a little will dissolve a great sulphureous body quickly and violently; and as other solvents, though but weak, quickly consume the dissoluble body, if the supply be renovated, so air, applied to a shining body by a bellows, will dissolve it as rapidly as saltpetre. From all which he concludes, that there is no such thing as an *element of fire*, but that flame results from the mutual agency of the volatile parts of combustibles, and a part of the atmosphere.

These although not the very words of HOOKE, but an abridgment of them, contain their unadulterated sense: his expressions show that he had experimented more largely upon the subject, but he was unwilling to extend his account of it till he had completely investigated other parts of the inquiry; he particularly alludes to the use of the air in respiration. I do not, however, find in any of HOOKE's later productions, that he followed up the interesting facts detailed in the *Micrographia*, though in his *Lampas*, published in 1677, he has given a beautiful explanation of the way in which a candle burns: he attributes the light and heat to the action of the air upon the combustible matter of the flame, and shows that the interior of the flame is not luminous, by the simple expedient of viewing its section through a thin piece of glass, or of mica.

The doctrines of HOOKE, concerning the influence of the air in combustion, were further illustrated by JOHN MAYOW†, who, in 1674, published his *Tracts on various Philosophical Subjects*. The date of this work is posterior to that of the *Micrographia*, but anterior to the *Lampas*, and it contains arguments very similar to those promulgated in the former work, without, as far as I have been able to find, any reference to them, or even mention of HOOKE's name. But MAYOW's chemical fame need not be built upon his doctrine of combustion, for he has displayed uncommon talents in various other branches of inquiry.

* New experiments touching the relation betwixt flame and air. BOYLE'S *Works*, 4to., London, 1772, p. 563.

† Born in Cornwall, 1645; died in London, 1679.

While these views were promulgating in England, and chemists were busy in endeavouring to raise a theory of combustion, independent of hypotheses, and founded upon experimental inferences only, BECCHER* and STAHL†, in Germany, were at work upon the same subject, and succeeded in establishing an explanation of combustion, which afterwards made much noise abroad, under the name of the *Phlogistic Theory*; and when we revert to the researches whence this theory, as it was called, arose, they carry with them so plausible and accurate an air, and appear so much less at variance with received doctrines, and known facts, that it is not surprising they should have been adopted in preference to the more abstruse and, as they then appeared, hypothetical explanations of HOOKE and MAYOW.

BECCHER'S *Physica Subterranea*‡ was published at Franckfort in 1669: I have endeavoured in vain to come at the meaning of much of this publication; but thus far is evident, that he has anticipated the prevailing geological theories of the present day, and has argued upon many terrestrial phenomena, with a degree of plausibility and precision which will bear comparison with the more enlightened and learned views of HUTTON and PLAYFAIR.

His notion of the chemical constitution of bodies amounts to this: the elements of bodies are air, water, and three earths, one of which is inflammable, another mercurial, and another fusible. The three earths, combined with water, constitute an universal acid, which is the basis of all other acids. The combination of two earths produces lapideous bodies; and, in the metals, the three earths are united in various proportions. I cannot pretend to explain or elucidate this doctrine, and have no further remark to make upon it, than to request it may be compared with the luminous experiments of HOOKE, in order to set the merits of the latter in their true light.

Towards the end of the seventeenth century, the opinions promulgated by STAHL attained universal assent, and of the names of HOOKE and MAYOW nothing was heard for more than half a century.

* Born at Spire in 1625; died in England, 1685.

† Born in Franconia, 1660; died at Berlin, 1734.

‡ Beccher wrote voluminously upon a great variety of subjects. His principal chemical works are as follows:

1. *Edipus Chemicus*. 2. *Metallurgia, de generatione, refinatione, et perfectione Metallorum*. 3. *Physica Subterranea*, and its various appendices. 4. *Parnassus Medicinalis Illustratus*. 5. *Laboratorium Portatile*. 6. *Chymischer Rosen-garten*.

Beccher's *Edipus* is dedicated to Francis Sylvius Deleboë, who, in 1658, was elected the first Professor of Medicine in the University of Leyden. He was a man of an acute mind, as appears from his various essays and tracts, more especially from his *Prælex Med. Idea Nova*. He died at Leyden in 1672.

"Utilissimum profecto munus subiisti, quo tui auditores non verba, sed corpora, non chymerasticos terminos, verum ipsas reales enchyrises, non inanes denique et immateriales facultates, sed a te demonstrati, effectus causas practicas audiunt, vident, tangunt." Beccher everywhere compliments him as a man not of words, but of deeds; as a philosopher, who eminently sought to render science popular and intelligible to all capacities.

The language of Beccher's *Physica Subterranea* is sufficiently inelegant and incorrect. "Excuso Latinitatem in hoc opere," says he, "quam barbaram esse fateor, ob materiem et ob scriptionem, in specie scriptionis modum: ex ore enim dictantis totum opus conceptum est. Sic rebus attentus, verba neglexi." This is at once an example and apology.

Rejecting the mercurial earth of BECCHER, STAHL retained as elements, water, acid, earth, and fire, or, as he termed it, *Phlogiston*, a principle of extreme tenuity, and prone to a kind of vibratory motion in which it appears as *fire*. He went beyond BECCHER in adducing experimental proofs of his hypothesis. When phosphorus is burned, it produces an acid matter with the evolution of much heat and light; consequently, phosphorus consists of acid and phlogiston: if this acid be now heated with charcoal or other body abounding in phlogiston, phosphorus will be re-produced.

When zinc is heated to redness, it burns with a brilliant flame, and is converted into a white earthy substance or calx. Hence zinc consists of this earth and phlogiston.

Now, it will be observed, that nothing is said here of the increase of weight which REY attributed to the condensation of air, and which MAYOW has as distinctly referred to the fixation of HOOKE'S nitro-aërial particles. Nor is that obstacle taken into the account which BOYLE'S experiments had suggested, and which HOOKE is particularly fond of dwelling upon, namely, that bodies will not burn without air.

However, this hypothesis of STAHL, notwithstanding the increase of weight in the burning body, the requisite presence of air, and other bars against it, was immediately embraced by the generality of chemists, and maintained an unimpeached dominion for upwards of fifty years, until shaken and upset by the arguments of LAVOISIER, who, availing himself of the discoveries of SCHEELE, PRIESTLEY, and BLACK, brought an insuperable mass of evidence to bear against the doctrine of phlogiston*.

That constituent of the air which HOOKE had detected in nitre, and which MAYOW called its nitro-aërial particles, was, under the new title of *oxygen*, regarded as accessory to all cases of combustion. It was presumed that this aërial matter consisted of heat and light, combined with a ponderable base, which united with the combustible, conferring upon it new characters, while the other elements were extricated under the form of fire. But to this explanation two difficulties soon presented themselves; the one, that in many cases of combustion, aëriiform matter, instead of being absorbed and decomposed, is evolved and composed; and the other, that the evolution of heat and light is not proportional to the volume of air condensed, but depends upon the rapidity of the condensation, and upon the nature of the combustible. These objections, however, cannot be fully discussed without a reference to the doctrines of heat, light, and electricity, which must not now be entered upon.

* Stahl's doctrines are very ably set forth in his *Three Hundred Experiments*, published at Berlin in 1731; and in his *Fundamenta Chemicæ*, Nuremberg, 1723 and 1732. He noticed the necessity of air to combustion, but he considered flame or fire as resulting from its violent ethereal agitations. Stahl is continually urging circumspection in hypotheses, yet preconceived opinions are always leading him to erroneous

conclusions, as the following passages amply prove. "Aer ignis est anima, hinc, sine aere nihil potest accendi vel inflammari."—"Aer in motum excitatus, seu ventus artificialis, vel etiam naturalis, mirum excitat motum ætheris seu flammam; hinc ad ignem fusorium, et vitrificatorium, promovendum, foliibus opus est; imo gradus et vehementia ignis dependet multum ex aeris admissione."—*Fund. Chem. dogmat. et ration.*, p. 22.

§ VI.

MAYOW, whose name was mentioned in the last section coupled with that of HOOKE, in researches concerning the influence of air upon combustion, is the first writer who divulged views worth recording upon the subject of respiration, and who has elsewhere displayed some shrewd guesses concerning the causes and effects of chemical affinity. In the first case, he opened a communication between chemistry and physiology; and, in the latter, he extricated a most important and fundamental branch of chemical philosophy from the mire of false reasoning, and planted it in the precincts of experimental research.

MAYOW was the ornament of his time and country as an experimental inquirer; but, unfortunately, he seems to have fallen upon unpropitious ground, and his talents, instead of having been awakened by emulation, were damped by the coldest reception. He was a native of Cornwall, and died at the early age of thirty-five, at the house of an apothecary in York-street, Covent garden. Dr. BEDDOES, and more lately, Dr. YEATS*, have each asserted his claims to several of the discoveries attributed to modern experimenters, and they have in many points made out an irresistible case in his favour.

At an early period of his experiments, MAYOW seems to have been struck with the analogy between the phenomena of combustion, and those of respiration, and although many of his conclusions are full of error, there are more which are correct and even refined. He burned a candle under a bell-glass, and found the air so deteriorated as to be unfit for the continuance of combustion. He then confined a mouse in a similar portion of air, and it soon manifested the want of its renewal. Then, by putting a mouse and a candle under the same bell-glass, he found it live only half the time that it had survived when under the glass alone. He then reversed the experiment, and endeavoured to fire combustible matter in air that had been spoiled by breathing; and finding that it would not burn, he observes, that "the nitro-aërial particles are absorbed both by the candle and the animal†."

Examining the residuary air standing over water after combustion, he found that it was a little lighter than the atmosphere, and extinguished flame; thus remarkably describing nitrogen by its principal properties, namely, that it does not support combustion, that it is not absorbed by water, and that its specific gravity is inferior to that of atmospheric air.

When MAYOW speaks of the *destruction of the elasticity* of a portion of the air, he alludes to its absorption by water; and finding the carbonic acid, formed by respiration and combustion, to be thus absorbed, and its formation always connected with the loss of power to support flame, or of its nitro-aërial parts, he talks of restoration of elasticity by restoring the nitro-aërial matter.

MAYOW also obtained hydrogen gas by acting upon iron by dilute

* *Observations on the Claims of the Moderns to some Discoveries in Chemistry, &c.* By J. D. YEATS, M.D. London, 1798,

† See the 1st and 2d Tracts, *De Sal-nitro, et Spirito Nitro-aërio*, and *De Respiratione*.

sulphuric acid; and nitrous gas, by immersing the same metal in dilute *aquafortis*. Upon the whole, MAYOW's experiments upon respiration, and upon the gases, are something more than ingenious. Considering the novelty of the subject, and the imperfection of his apparatus, they may be considered as surprising efforts of experimental diligence, and his conclusions may be ranked as remarkable indications of a fruitful mind, not wandering amongst hypotheses, but settling upon the results of experiment. Not satisfied with having ascertained that one part only of the atmosphere supports life, he extended his inquiry to the subsequent influence of that part upon the system. It was the prevailing notion of his time that respiration cooled the blood, but having observed in the nitro-aërial or fire-air particles an essential to flame and fire, he considered their absorption as necessarily connected with the heat of the blood; he observed an analogy between the respiration of animals and that of plants; and to show the existence of air in the blood, he had recourse to the air-pump, which, he says, extricates it more copiously from arterial than from venous blood.

The most remarkable Chapter, however, of MAYOW's tract, is that relating to the "mutual action of salts of contrary kinds," or, in other words, to chemical combination and decomposition, a subject which he has handled in so masterly a manner, and which is so ably supported by experiments, that, although anticipated in respect to his researches on the air by HOOKE, we must here give him due credit as an original inquirer.

It was imagined by those predecessors of MAYOW who expounded their notions respecting chemical affinity, that bodies combined in consequence of certain mechanical forms of their particles; and that when an acid was added to an alkali, the salt produced was a perfectly new product, resulting from the *annihilation* of the particles of its components. It was not admitted, or at least not generally admitted, that the acid and alkali existed as such, and might again be separated from the neutral salt. MAYOW first set about rectifying this gross error. When spirit of salt, he says, is mixed with *sal volatile*, sal ammoniac is produced, in which, it is true, neither the properties of acid, nor of alkali, are apparent; yet, if salt of tartar be distilled with sal ammoniac, the volatile alkali will be displaced with all its previous characters, because there is a greater attraction between spirit of salt and tartar than between spirit of salt and volatile alkali. Again, to show that the acid is not destroyed in saline combinations, he instances the decomposition of nitre by oil of vitriol, which, he says, displaces the nitric acid, and the residuum in the retort furnishes vitriolated tartar. It may be asked, he says, why, when nitre is heated, the nitric acid does not rise, for it is, as we have just seen, very volatile: the reason is, that it is restrained and kept down by its attraction for the tartar, and can only be displaced by bodies which have a stronger attraction for tartar than it. This is excellent reasoning, and it would be difficult, with all the advantages of modern acquisitions, to adduce two more illustrative cases than those which MAYOW has furnished. He then goes on to show that acids have a greater attraction for alkalies than for metals. The metals, he says, are soluble in one or other of the acids, but their solutions are decomposed by salt of tartar; the acid then combines with the tartar, and the metal is precipitated. In the same way

alkali unites to sulphur; but if this combination be dissolved in water, and acid added to the solution, the sulphur falls, and the acid and alkali unite. Combinations of the metals with sulphur are also decomposed by acids; thus, if sulphuret of antimony be distilled with aquafortis, the acid and metal combine, and sulphur sublimes.

Having given other similar instances of the combination of sulphur with metals and alkalies, he proceeds to some general views connected with the subject, among which the following deserve particular notice. Although, he says, sulphur enters into these combinations, we are not to imagine, as some have done, that sulphur includes an acid, and thence derives its powers of combination, in consequence of its containing an opposite nature; on the other hand, it is clear, he adds, that the combination is independent of any such hidden cause, and is the mere result of the mutual affinity of the substances. He then cautions those concerned in the compounding of medicines, to beware of the new compounds that may result in consequence of these mutual attractions and decompositions, for "one substance may destroy the efficacy of another, and something perfectly different from the original may result." It is curious, he remarks, that when acid of vitriol is poured upon salt of tartar, so as to form vitriolated tartar, a great effervescence ensues; but if the acid be previously combined with a metal, this is not observed, and yet vitriolated tartar is equally formed; as when salt of tartar is added to solution of green vitriol. In these cases, he says, the acid part of the salt of tartar is retained by the metal; thus giving an explicit account of a frequently occurring case of double decomposition.

These views, relating to chemical attraction, are at once clever and correct, and their merit will be especially enhanced by a comparison with the absurd and groundless speculations previously entertained upon this subject. But MAYOW has other and more weighty evidence in his favour, for it is remarkable that his views and language were adopted by NEWTON, and that the sketch of a theory of chemical attraction given by that philosopher in the Queries annexed to the third book of Optics, is nearly in the language, and quite in the spirit and meaning, of his predecessor MAYOW. The following are a few of the points urged by NEWTON in the explication of these phenomena:—

If carbonate of potash be exposed to air it deliquesces, in consequence, says NEWTON, of an attraction between the salt and the particles of water contained in the atmosphere. And why does not common salt and saltpetre deliquesce in the same way, except for want of such attraction?

And again, where he especially comes in contact with MAYOW, he says, when spirit of vitriol, poured upon common salt or saltpetre, makes an ebullition, and affords on distillation the muriatic and nitric acids, the acid part of the spirit of vitriol staying behind, does not this argue that the fixed alkali in the common salt and saltpetre attracts the acid spirit of the vitriol more strongly than its own spirit, and not being able to hold them both, lets go its own? How these attractions may be performed, continues NEWTON, I do not here consider; what I call *attraction* may be performed by impulse, or by some other means unknown to me: I use that word to signify any force by which bodies tend towards one another, whatever be the cause. Thus, he says, muriatic acid unites to

salt of tartar, by virtue of their respective attractions; but when oil of vitriol is poured upon this compound, the former acid is displaced by the superior attraction of the latter. Silver is separated from aquafortis by quicksilver; quicksilver by copper; and copper by iron; which argues that the acid particles of the aquafortis are attracted more strongly by iron than by copper; by copper than by quicksilver; and by quicksilver than by silver*. Thus, then, chiefly by the experimental labours of MAYOW, and the sagacious views of NEWTON, the old and prevailing notions of the atomic forms of bodies, the hypothesis of hooks, rings, points, and wedges, by which the component parts of bodies were supposed to be held united, gave way to a simple and independent expression of facts.

It has often been said, that anticipations of modern discoveries which could alone be demonstrated by the progress of experimental research, are characteristic of the writings of NEWTON, and proofs of his sagacity and penetration: he inferred that the diamond consisted of inflammable matter, and suspected the existence of a combustible element in water, very long before either of those subjects had been experimentally investigated; and in his notions relating to the subject of chemical attraction, he has an anticipation not less striking, relating to the connexion between chemical and electrical attraction. "The attractions of gravity, magnetism, and electricity, reach to very sensible distances, and so have been observed by vulgar eyes; and there may be others which reach to so small distances as hitherto to escape observation, and perhaps electrical attraction may reach to such small distances without being excited by friction†."

I shall conclude this subject with some account of the progress more lately made in elucidating the doctrines of chemical attraction.

In 1718, GEOFFROY‡ invented those tables of affinity which are now often given in elementary works, and which have proved of service in extending chemical knowledge; he considered the order in which bodies separate each other from a given body, as constant. Thus, he thought the metals were always separated from acids by the absorbent earths, these by volatile alkali, and the volatile by the fixed alkalies; to represent, therefore, the attraction of acids for these substances, he placed them at the head of a column, with the other bodies beneath, in the order of attraction, as shown in the margin.

He then constructed a column for each particular acid; thus the table for nitric acid taken from NEWTON's experiments would stand as annexed:—

GELLERT and LIMBOURG, in 1751 and 1758, extended and, in some respects, improved these tabular representations of the results of attraction; but no considerable progress was made in the investigations connected with the subject, until BERGMAN published his dissertation upon it in 1775.

Of BERGMAN'S character and merits as a chemist, I shall speak afterwards, confining myself at present to the views which he entertained upon the subject of affinity, or, as he called it, *elective attraction**.

BERGMAN considered that every substance possessed a peculiar attractive force for every other substance with which it combines; a force capable of being represented numerically: he regarded decomposition as complete; that is, whenever a third body *c* is added to a compound *a, b*, for one of the constituents of which it has a stronger attraction than that which already exists between them, the compound will be decomposed, and the whole of one of its elements transferred to the added body. Thus, suppose the attraction of *a* for *b* to be represented by 1, and of *a* for *c* by 2, then the addition of *c* to *a b* will produce the compound *a c*, and *b* will be separated. When lime-water is added to nitrate of magnesia, the latter earth is precipitated, and the former combines with the nitric acid. Hence, nitric acid poured upon a mixture of lime and magnesia, dissolves the former, in preference to the latter earth.

The observation of these facts led BERGMAN to call this kind of attraction *elective*, and he has given tables, showing these relative attractions of bodies in the dry and humid way. Thus:

BERGMAN'S opinions relating to affinity were generally admitted as correct, till BERTHOLLET published his work on *Chemical Statics* in 1803, in which he endeavoured

to revive, under a new aspect, some of the old chemico-mechanical doctrines, and to prove that the forms of the acting particles, and their magnitude, or masses of matter, were concerned in influencing the results. Though these doctrines may now be considered as disproved, they had many advocates, and were gaining ground, until the promulgation of the theory of definite proportionals. The experiments adduced by BERTHOLLET in support of his hypothesis, appeared at first very satisfactory; but upon minute inspection they have their weak points, and many of the errors into which they led have been successfully unravelled by Professor PFAFF, of Kiel; by Sir H. DAVY, and others. In illustration of the agency of the mass of matter, BERTHOLLET has adduced the mutual action of sulphate of potassa and baryta: when solution of baryta is added to sulphate of potassa, potassa is liberated; and sulphate of baryta is formed and precipitated insoluble; but if a large quantity of potassa be added to a small quantity of sulphate of baryta, the mass will, according to BERTHOLLET, prevail over what appears to be the real chemical affinity, and sulphate of potassa will be formed, and baryta evolved. But Sir H. DAVY pointed out the fallacy to which this experiment is liable, by showing that pure potassa does not effect any change upon sulphate of baryta, but that, making the experiment in open vessels, part of the potassa acquires carbonic acid, and then a double affinity is brought into action, the bodies present being carbonate of potassa and sulphate of baryta†.

* *De Attractionibus Electivis. Opus-*
cula, vol. iii., p. 291.

† *Elements of Chem. Philos.*, p. 119.

BERTHOLLET's notion, that the acting bodies are divided among each other in proportions, depending upon their relative masses and attractions, has been combated and disproved by PFAFF*, who has shown that tartrate of lime is completely decomposed, by adding to it a quantity of sulphuric acid, exactly sufficient to saturate the lime it contains; and in the same way he has shown that oxalate of lead is decomposed, by adding sulphuric acid sufficient to saturate the oxide of lead.

But the establishment of the Atomic Theory, from which we learn that bodies combine only in certain definite proportions, has gone further to elucidate the important subject of chemical attraction, and to subvert former doctrines, than any previous objections or partial experimental investigations. In establishing this theory, all the eminent chemists of Europe have taken an active part. Its foundation was apparently laid by Mr. William Higgins of Dublin, previous to the year 1789; for the essential facts, which have subsequently been followed up, and worked out by later chemists, are to be found in his *Comparative View of the Phlogistic and Antiphlogistic Theories*. In the year 1814, he published his *Experiments and Observations on the Atomic Theory*, to which I may also refer the historical reader.

Between the years 1792 and 1802, Dr. RICHTER†, of Berlin, published his *Geometry of the Chemical Elements*, containing a series of tables, showing the weight of each base capable of saturating one hundred parts of each acid; and the weight of each acid capable of saturating one hundred of each base. He observed, that in all these tables the bases and the acids followed the same order: and further, that the numbers in each table constitute a series having the same ratio to each other in all the tables. Thus, supposing in the table of sulphates, one hundred parts of acid were saturated by one hundred of soda, two hundred of potassa, and three hundred of baryta; then in the table of nitrates the same ratio would hold good, and the soda, potassa, and baryta would there also stand to each other in the relation of one, two, and three.

Thus was explained why, when two neutral salts decomposed each other, the newly formed salts are also neutral; for the same *proportion* of bases that saturate a given weight of one acid, saturate a given weight also of all the other acids. Hence numbers may be attached to each acid and to each base, indicating the weight of it which will saturate the numbers attached to all the other acids and bases. Upon this principle, elementary works on chemistry contain tables of the representative or equivalent numbers of bodies; and upon the same principle, Dr. WOLLASTON, by adapting such table of numbers to a moveable scale, on the principle of GUNTER's sliding rule, has constructed the *logometric scale of chemical equivalents*, which is so important and valuable an instrument to the practical chemist.

I cannot enter into further details respecting the researches which have established and elucidated this highly important subject, without entering into discussions involving the labours of contemporary chemists; and must, therefore, here, merely refer to the investigations of Dalton‡

* *Annales de Chimie*. LXXVII.

and Gay Lussac* connected with it, and to the details which will be found in another part of this work.

§ VII.

BEFORE we proceed with the regular thread of our historical sketch which is now carrying us into that eventful period for chemistry, and indeed for the progress of all the sciences, the first half of the eighteenth century, it is requisite rapidly to review some collateral investigations which occupied the philosophers of the seventeenth century, and which, though not strictly chemical, contributed much to the progress and perfection of some of the more difficult and abstruse branches of that department of knowledge.

Of these inquiries it will especially be right to notice such as relate to the phenomena and effects of *heat*, which, in consequence chiefly of the invention of the *thermometer*, were pursued with a degree of ardour and success, highly creditable to the diligence and sagacity of the individuals concerned. Among them, BOYLE is entitled to particular praise; and though his inquiries are blended with much irrelevant and miscellaneous digression, they contain materials amply important and interesting; materials which paved the way for some of the most eminent achievements in chemical science.

It has been disputed to whom the honour of inventing the thermometer belongs; some have given it to CORNELIUS DREBBEL†, and some, with more plausibility, to SANTORIO‡ of Padua. But, when we reflect upon the imperfection and comparative uselessness of the instruments attributed to those claimants, and when the construction of the thermometer now in use may be indisputably referred to the Florentine Academicians, the disputes respecting priority become of little importance. Air was first used as a means of exhibiting, by its expansion and contraction, the alternations of heat and cold; and VAN HELMONT has described, with some minuteness, several modifications of the *air thermometer*§. But however valuable such thermometers may be for particular purposes, they are rendered extremely inconvenient by the rapid and great dilatibility of air by moderate changes of temperature: besides which, it is very difficult so to construct air thermometers as to agree among themselves in indicating the same degree, when applied to bodies of similar temperature. The Academicians del Cimento were the first to employ thermometers constructed as we now see them. They used tubes, with a bulb containing spirit of wine, and closed so as to exclude the influence of air, and prevent the evaporation of the liquid. This thermometer, however, though much superior to, and more useful than the old air thermometer, was yet an useless instrument, if we speak of it comparatively with those now constructed; for, there being no fixed point at either extremity of the scale, the graduation was arbitrary, and no two instruments, when placed in an atmosphere of the same temperature, indicated the same degree of heat.

* *Mémoires d'Arcueil*, ii. 287.

† Born in Holland, 1572; died in London, 1634. He is also said to have invented the microscope.

‡ Born at Capo d'Istria, 1561; died at Venice, 1636.

§ *Opera Omnia*, Art. Aër, p. 61.

There is some confusion in this part of the history of the thermometer, for, though the Florentine Academicians state that their scale generally commenced at the temperature of freezing, they represent that point by various terms or degrees, unsusceptible of comparison, and say nothing of the differing temperature of ice, which may exist at 32° , or any inferior degree. In Italy, however, it is most probable that the ice was in a thawing state, and therefore about 32° of FAHRENHEIT'S scale; but all registers of the weather, and all enumerations of high and low temperatures, are quite unintelligible, as recorded by the experimentalists of that period.

"The great and truly honourable Mr. BOYLE" turned his mind with much earnestness to the construction of a *scale* for thermometers, and seems to have had it in contemplation to set out with the temperature at which water *begins* to freeze; "but the objections which he apprehended might be made to this method scared him so much," says Dr. MARTINE*, "that he prosecuted no further this consideration of fixing a standard for making and graduating thermometers all in the same way." Dr. HALLEY† observed, that the same thermometer always indicated the same temperature in places deep under ground, where neither the heat of summer nor the cold of winter seemed to produce any effect; and MARRIOTTE and DE LA HIRE had made the same remark upon thermometers placed in the caves of the observatory at Paris. But Dr. MARTINE, whose authority is, in most respects, very exact, gives Dr. HALLEY the merit of fixing upon the boiling point of water as a standard of graduation, which elevates the quicksilver in the thermometer tube always to a given point, under given barometrical pressure; and the mean pressure of 30 inches of mercury is generally understood to be that to which our thermometers are graduated. Sir I. NEWTON employed the freezing and boiling of water as fixed points, but he used linseed oil to fill his tubes, a liquid inconvenient from its viscosity, and irregularity of expansion. Alcohol was first used by the Florentine Academicians, because it is very sensible to changes of temperature, and remains clear in the tube; but, since its boiling point is much below that of water, it is useless for the measurement of high temperatures, though, from not freezing, well suited to indicate extreme cold. For general convenience and equability of expansion, mercury, first used, I believe, by Dr. HALLEY, takes precedence of all other liquids. It bears nearly a red heat before it boils, and sustains the cold of these latitudes without freezing; hence it is the liquid generally used for accurate and delicate thermometers.

The principal thermometric scales in use in Europe are, FAHRENHEIT'S, which commences at the temperature produced by mixing snow and salt, and which is 32° below the freezing of water, so that the latter point is marked 32° , and the boiling point 212° , the intermediate space being divided into 180° : REAUMUR'S, in which the zero is the freezing point, and 80° the boiling point: and the *Centigrade*, in which the space between the freezing and boiling of water is divided into 100° , the freezing point being 0° and the boiling point of water 100° .

In this country, FAHRENHEIT'S scale is in general use; over the greater part of Germany, REAUMUR'S scale is employed; and in France, the *Centi-*

* *Essays, Medical and Philosophical.* | † *Phil. Trans.*, Abr. ii., p. 36.
By G. MARTINE, M.D, London, 1740.

grade: it is much to be desired that the subject of a thermometric scale should, in the present advanced state of science as regards the doctrine of heat, be taken into consideration, and that either the *Centigrade* (which is certainly the least objectionable of those hitherto used) or some analogous scale should be universally employed.

There are other circumstances connected with the construction and indications of the thermometer, which I reserve for notice till we consider the more refined investigations relating to the subject of heat, undertaken at a subsequent period: in the meantime we may advert to the discovery of a singular property possessed by water, which, as far as concerns the influence of heat upon it, distinguishes it from other liquids. This anomaly was first observed by the Florentine Academicians: "We know," they say, "that water, in passing into the state of ice, suffers great expansion, a fact sufficiently evident from the violence with which various vessels are broken and rent asunder during the freezing of water in them; but it was not known to us at what particular period of refrigeration this expansion occurs; nor could we learn it from our former experiments, which were made in vessels of silver, gold, brass, and other strong, but opaque materials. We, therefore, now employed glass flasks, and observed, that the moment they were immersed in ice, the water in the neck of the flask was suddenly elevated, that it then began gradually to fall, and at length remained for a few moments quite stationary; then it began again to rise with a slow, but apparently equable progress at first, but afterwards sprung up so suddenly, that the eye could scarcely follow it*."

In BIRCH's *History of the Royal Society*, under the date of the 6th of February, 1683, we find some experiments on the freezing of water made

* The following unaffected narrative of this celebrated experiment is very different from the usual verbose and pompous style of the philosophers of the period.

"Già sapevamo per innanzi (e lo sa ognuno) che il freddo da principio opera in tutti i liquori ristignimento, e diminuzione di mole, e di ciò non solamente n'avevamo la riprova ordinaria dell' aquarzente de' Termometri, ma n'avevamo fatta esperienza nell' acqua, nell' olio, nell' argentovivo, ed in molti altri fluidi. Dall' altro canto sapevamo ancora, che nel passaggio, che fa l' acqua dall' esser semplicemente fredda al rimuoversi dalla sua fluidità, e ricever consistenza, e durezza coll' agghiacciamento, non solo ritorna alla mole, ch' ell' aveva prima di raffreddarsi, ma trapassa ad una maggiore, mentre se le veggono rompere vasi di vetro e di metallo con tanta forza. Ma qual poi si fosse il periodo di queste varie alterazioni, che in essa opera il freddo, questo non sapevamo ancora, ne era possibile d'arrivarvi con agghiacciarla dentro a' vasi opachi, come quei d'ar-

gento, d'ottone, e d'oro, ne quali s'era fin' allora agghiacciata: Onde per non mancare di quella notizia, che pareva esser l'anima di tutte quest' esperienze, ricorremmo al cristallo, ed al vetro, sperando per la trasparenza della materia d'aver presto add' assicurarci come la cosa andasse, mentre si poteva a ciascun movimento, che fosse apparso nell' acqua del collo, cavar subito la palla dal ghiaccio, e riconoscer in essa quali alterazioni gli corrispondessero. Ma la verità si è, che noi stentammo assai più che non ci saremmo mai dati ad intendere, prima di poter rinvenire alcuna cosa di certo intorno a' periodi di questi accidenti. E per dirne più distintamente, il successo è da sapere, che nella prima immersione, che facevamo della palla, subito, ch' ella toccava l'acqua del ghiaccio s'osservava nell' acqua del collo un piccolo sollevamento, ma assai veloce, dopo il quale con moto assai ordinato, e di mezzana velocità s'andava ritirando verso la palla, finchè arrivata a un certo grado non proseguiva più oltre a discendere, ma si fermava quivi per qualche tempo, a

before that body, in consequence of a letter received from Mr. MUSGRAVE, of Oxford. "Dr. CROUNE said, he had observed water put into a bolt-head rise higher before freezing. Mr. HOOKE attributed this to the shrinking of the glass. Dr. C. said, the glass had been long in the cold before, and the water rose immediately. Dr. WALLIS proposed that an empty glass might be well cooled in a freezing liquor, in order that it might have its contraction before the water be put into it. This was done immediately by Mr. HUNT, and the water being put into a small bolt-head rose in the neck." Numerous and correct experiments have completely established this peculiarity in the freezing of water; other fluids have their maximum of density just before the freezing point; water expands before it freezes, and consequently water at 36° is lighter than water at 40° , and floats upon its surface; hence it is, that large masses of water, being cooled by the atmosphere upon their surface, only freeze there, and the water beneath retains the more congenial temperature of 40° .

Among the experiments made by the *Accademia del Cimento*, we find many details independent of those already adverted to, which are at once accurate and curious, and especially in that section of their *Transactions*, entitled *Experiments relating to Ice*. In the sixth experiment of this section they notice the effect of various metallic vessels upon the thawing of ice: they found it was longer preserved in lead and tin than in similar vessels of brass and of iron; and that it soon thawed in gold, and sooner in silver. This enumeration of the metals is in the order of their conducting power, as ascertained more than a century afterwards by Dr. INGENHOUSZ.

The radiation, reflection, and refraction of heat, are subjects of inquiry which also probably engaged much of the attention of the Florentine experimentalists, but their published essays contain scarcely any details relating to them. In the ninth experiment, however, of the above quoted section, they have given an account of a discovery that afterwards excited much discussion, relating to the reflection and radiation of cold. "We were anxious to try if a concave mirror, placed before a mass of ice, weighing five hundred pounds, caused any reflection of cold upon a very delicate thermometer placed in its focus; and truly it began immediately to fall; but in consequence of the vicinity of the ice, it was doubtful whether the effect resulted from the direct or from the reflected rays; we, therefore, covered the mirror, and whatever was the cause, certain it is that the spirit began immediately to rise again. With all this, we do not mean positively to affirm that no other cause could have produced such an effect than the absence of the rays reflected from the mirror, for we were not careful in adopting all the precautions requisite in such an experiment*."

giudizio degli occhi, affatto priva di movimento. Poi a poco a poco si vedea ricominciare a salire, ma con un moto tardissimo, e apparentemente equabile, dal quale senz'alcun proporzionale acceleramento spiccava in un subito un furiosissimo salto, nel qual tempo era impossibile tenerle dietro coll'occhio, scorrendo con quell'impeto, per così dire,

in istanti le decine e le decine de' gradi. *Esperienze intorno al progresso degli artificiali agghiacciamenti, e de' loro mirabili accidenti. Saggi di naturali esperienze fatte nell'accademia Del Cimento.*—Firenze, 1691.

* *Saggi*, above quoted. See also Waller's Translation of the *Essays of the Academicians del Cimento*. 1684.

MUSCHENBROEK, DE MAIRAN, and others, concluded from these and similar experiments, that cold is not the mere absence of heat, but a distinct form of matter possessed of specific properties. Sometimes it has been spoken of as a substance of a saline nature, floating in minute particles in the air, and occasioning the congelation of water by intruding themselves among its particles. Now, although such a conclusion is not called for by the phenomena, it has been plausibly conjectured that ice and other cold bodies do radiate matter, which is capable of exciting the sensation of cold in circumjacent bodies.

To get rid, however, of such an hypothesis, it has been suggested that the effect of the ice is to disturb the balance of temperature in the surrounding bodies, and consequently to cause a chasm, as it were, into which they tend to pour their excess of heat; among these is the thermometer, which consequently indicates cold: but although such an explanation might suffice in respect to the mere approximation of the ice to the thermometer, it is scarcely applicable to the case of radiation.

Sir H. DAVY says, "the apparent radiation of cold is in harmony with the phenomena of the reflection of the solar beams; for if it be supposed that rays capable of producing heat emanate from all terrestrial bodies, but in quantities greater in some increasing proportion as their temperatures are higher, then the introduction of a cold body into the focus of one mirror ought to diminish the temperature of a thermometer in the focus of the other, in the same manner as a black body placed in one focus would diminish the quantity of light in the other focus; and the eye is to the rays producing light, a measure similar to that which the thermometer is to rays producing heat*."

LESLIE admits that the temperature excited by radiant matter varies with its source, and that all substances may be considered as producing these emanations. If we approach a heated surface, we feel the radiant heat; if the surface be of the same temperature as ordinary circumjacent bodies, or of a temperature between 40° and 80° , we feel, perhaps, nothing remarkable; yet such a surface does actually radiate matter of its own temperature, as shown by approaching it with a cooler thermometer: if the surface be of ice or colder materials, we feel upon approaching it the sensation of cold, depending upon the emanation of cold radiant matter, since it is susceptible of reflection by the mirrors. We are further to consider, that the terms *heat* and *cold* are merely relative. We may suppose that in an atmosphere heated to 400° , boiling water would radiate (comparatively speaking) cold; and in the same way ice at 32° would radiate heat in an atmosphere very much below the freezing point. To LESLIE we are indebted for an admirable series of researches on the philosophy of radiant matter, partly contained in his *Treatise on Heat*, and partly in other essays, (*Suppl. to Encyclop. Brit.*) He supports the theory of the radiation of cold by some striking illustrations.

§ VIII.

FROM the preceding details, some idea may be formed of the state of chemistry at the close of the seventeenth century. As an art, we have

* *Elements of Chemical Philosophy*, p. 206.

seen with what success and diligence it was cultivated by BASIL VALENTINE and GLAUBER; and how ably it was pursued as a science by MAYOW and HOOKE. To these philosophers, and to a few of their companions, we not only owe the materials which were arranged and embodied by their earliest successors in the eighteenth century, but we are to ascribe also to them the merit of founding scientific chemistry; of laying the basis upon which the superstructure of modern chemical science has been raised. The importance of multiplied observations and experiments, the application of chemical principles to agriculture, and the aid to be derived from them in several arts and manufactures, as well as in many departments of domestic economy, are to be learned in the writings of GLAUBER; while BASIL VALENTINE and VAN HELMONT have shown the necessity of studying pharmacy on chemical principles, and have applied, with much success, the doctrines learnt in the laboratory, to the preparation of many invaluable medicines, which have facilitated the treatment and cure of disease; nor were the quackery and eccentricities of PARACELSUS unemployed in this reformation. In that age, example was more efficacious than precept; and those who witnessed the cures which he performed, enlisted under his banner, and were equally vehement with their leader in combating the doctrines of the Galenical school of physic, and substituting those of the chemical sect.

If we look at the scientific generalizations of modern chemistry, and more especially at the theories of combustion and acidification promulgated by the French school, about the middle of the last century, we find them not anticipated merely, but even minutely explained, by BOYLE, HOOKE, and MAYOW, who flourished about one hundred years before LAVOISIER; and MAYOW, in his researches into the laws and phenomena of chemical affinity, seems to have trodden upon ground which even NEWTON explored as his own. In the history of chemistry, we perceive perhaps, more than in any other branch of science, the different roads by which the human mind arrives at the same conclusions; but we are not therefore to consider those conclusions as unavailing, because anticipated; the very circumstance of attaining them by different means, justifies the search; and he whose investigations disclose new views, and unfold new truths, may rest satisfied that he has not laboured in vain, because he ultimately arrives where others have been before him. In estimating, however, the true merits of chemical discoveries and inventions, and more especially in determining the excellence and originality of theories, it is requisite to look to their sources, and to examine the steps which lead to them, and upon that examination to found our opinion.

The leading feature and important novelty of the science, as influencing its progress in the last century, was certainly the discovery of gaseous bodies, and the perfection of pneumatic chemistry; without which analysis could have made little progress, and, independent of which, all improvement in theory would have been but slow and ineffectual; it was also materially, though less directly assisted by those investigations respecting the agency of heat, in which Dr. BLACK made himself so eminent.

Though something is due to MAYOW, we must in justice confer the merit of founding *pneumatic chemistry* upon Dr. STEPHEN HALES*, whose

* Born in Kent, 1677; died at Teddington, 1761.

researches came before the public very early in the last century. "He refused a canonry of Windsor, that he might continue to devote himself to his parochial duties, and favourite scientific pursuits; and, as piety, truth, and virtue, were the principles of his character, he lived in universal esteem to the age of eighty-four, dying at Teddington, on the 4th of January, 1761, where he was buried, under the church-tower, which he had rebuilt at his own expense."

Dr. HALES commenced the communication of his researches to the Royal Society about the year 1717, and, in 1727, he published his *Statistical Essays, containing an Essay towards a Natural History of Vegetation, of use to those who are curious in the Culture and Improvement of Gardening: also a Specimen of an Attempt to analyse the Air, by a great variety of Chemico-Statistical Experiments, which were read at several Meetings before the Royal Society*. In 1733, a second volume of these Essays was published, containing *Hæmastatics, and Experiments on the Stone of the Kidney and Bladder*. Of these Essays, it will be first necessary to advert to the contents of those relating to the analysis of the air, a term, by the way, which by no means well applies to the researches they contain.

Dr. HALES employed several methods of collecting and examining the gaseous products of a variety of bodies, many of which approach those at present in use. Sometimes he placed substances upon a stand, under a bell-glass inverted over water; or he employed a flask to contain the materials producing æriform matter, over which was placed a bell-glass, the whole being confined over water as before. Or where a high temperature was required for the production of the gaseous bodies, he used an iron retort formed of a bent gun-barrel, and received the air into a vessel inverted in a tub of water. In the modification and management of these forms of apparatus, he displayed some ingenuity; but it should be remembered that he was anticipated in the greater number of his contrivances by MAYOW, as we have already had occasion to remark.

In prosecuting his inquiries by these means, Dr. HALES stumbled upon a variety of curious facts and observations; but having unluckily predetermined that the various products formed were mere modifications and contaminations of common air, he let slip a numerous series of discoveries once fairly within his grasp, and which were afterwards eagerly amassed and successfully reasoned upon by PRIESTLEY and his contemporaries. Thus, Dr. HALES observed that phosphorus when burned, absorbed air, and produced white fumes; but he neglected any examination of the product and of the residue. He distilled air from wood, and found it fatal to animals; from Newcastle coal he obtained one-third its weight of gas; from nitre, one hundred and eighty times its bulk; and from salt of tartar urged by an intense heat, he also procured æriform matter; but in no one instance did he examine these gaseous products with the attention that might have been expected from an experimentalist so diligent and original. He found that iron filings and oil of vitriol produced scarcely any air; but that, upon the addition of water, gas was abundantly evolved from such a mixture. Here he obtained hydrogen, but instead of stopping to examine its properties, he hastens on to irrelevant observations, and seems always eager rather to multiply experiments

than to examine their results. Upon the same principle, he accurately details the quantity of air generated by distilling hog's blood, tallow, sal ammoniac, oyster-shells, Indian wheat, pease, mustard-seed, amber, tobacco, sugar, bees' wax, and gall-stones; and yet, from such numerous experiments, he scarcely draws a single inference that deserves to be recorded.

In his experiments on respiration, Dr. HALES obtained results of such interest, that one is surprised at the coldness with which he pursued them, and the carelessness with which he drops the inquiry. Finding that a given portion of air could only be respired for a given time, and that it soon produced oppression and difficulty of breathing, in consequence, as he says, "of the gross and sulphureous vapours with which it becomes loaded," he endeavoured to discover some substance which, by absorbing those vapours, might render respired air more fit for breathing, and consequently contribute to its purification in small and crowded rooms, and other similar situations. The apparatus which he used in these researches was sufficiently ingenious; it consisted of a bag made of bladder, with a mouth-piece so supplied with valves as to oblige the air breathed into it to traverse its whole length, before it could return to the lungs. He found that he could breathe the air contained in this apparatus to and fro, for a minute and a half; he then wetted certain diaphragms or partitions of flannel in the bag, with different liquids, and found that he was thus enabled to respire the confined air for rather a longer time; but having dipped them in a solution of highly calcined tartar, he found he could, without much inconvenience, continue the breathing for eight minutes and a half.

It is probable that the air was purified in this instance by the absorption of the carbonic acid; or to use Dr. HALES' language, "of the sulphureous gross vapours;" but, unwilling as he always appears to follow up and investigate the new facts, he says, that the effect was perhaps owing to the bladder and syphon being entirely dry, or to some unheeded passage for the air through the ligatures,—“neither did I care to ascertain the matter by repeated experiments, fearing I might thereby some way injure my lungs.” He however weighed the diaphragms, and found that they had increased in weight about thirty grains in five minutes, making the quantity of matter absorbed by them from the expired air, amount to nineteen ounces in twenty-four hours. In other experiments, the author notices the purification of air spoiled by the burning of candles and of brimstone, by the action of calcined tartar; but he takes no pains to inquire into the specific action of the salt, and confounds it with that of saline bodies generally.

But Dr. HALES' researches relating to the motion of sap in vegetables, are in a great measure free from the objections which may be made to his other experimental inquiries, and were pursued upon a more regular and digested plan. His first object seems to have been to ascertain the quantities of matter imbibed or perspired by plants and trees; for this purpose he grew a sunflower in soil contained in a tight box, and watering it with given weights of water, he ascertained the quantity that it daily lost by transpiration from the leaves: after stating the extent of surface of the leaves, he informs us, that its minimum of loss by that chan-

nel was sixteen ounces, and its maximum twenty-eight ounces, in a day of twelve hours. To ascertain more particularly the influence of the leaves upon the absorption of water by the root, two branches, one with and one without leaves, were put into separate glasses, containing known quantities of water. The boughs with leaves absorbed on an average from twenty to twenty-five ounces in a day, and were lighter at night than in the morning; those without leaves imbibed but one ounce, and were heavier in the evening than in the morning. This experiment led to the inference, that the ascent of the sap, and the quantity of matter absorbed from the soil, are much influenced by the leaves; "and accordingly I observe," he says, "that the leaves next adjoining to blossoms are in the Spring very much expanded, when the other leaves on barren shoots are but beginning to shoot; and that all peach-leaves are pretty large before the blossom goes off: and that in apples or pears, the leaves are one-third or half-grown before the blossom blows: so provident is Nature in making timely provision for the nourishing of the yet embryo fruit." A certain degree of dryness of air is requisite to promote the due transpiration by the leaves, for when too much moisture hovers about the plant, it hinders the kindly action of the leaves, "whereby," says Dr. HALES, "the stagnating sap corrupts and breeds mouldy fen, which often spoils vast quantities of flourishing hop-grounds. This was the case in the year 1723, when ten or fourteen days' almost continual rain fell, about the latter half of July, after four months' dry weather; upon which the most flourishing and promising hops were all infected with mould or fen in their leaves and fruit, while the then poor and unpromising hops escaped and produced plenty, because they being small did not perspire so great a quantity as the others." "This rain on the then warm earth made the grass shoot out as fast as if it were in a hot-bed, and the apples grew so precipitately, that they were of a very flashy constitution, so as to rot more remarkably than has ever been remembered."

In the course of his experiments upon the transpiration of plants, and their absorbing powers, Dr. HALES endeavoured, but always without success, to alter the flavour of their fruit by causing them to imbibe various perfumes. He placed a vessel upon a divided branch of a tree, so that it might absorb any fluid contained in it. Upon filling it with camphorated spirit of wine, the whole branch of an apple-tree was killed; but, though the apples hung several weeks afterwards, no alteration of taste was perceived in them, though the smell of camphor was strong in the leaf-stalks, and all other parts of the dead branch. Different perfumed waters were absorbed by fruit-trees without injuring them, but they failed to confer any peculiar flavour on the fruit.

If, as Dr. HALES' experiments seemed to show, the transpiration of plants, and the motion of the sap, as well as the absorption from the soil, depend upon the leaves, it became an interesting question to examine these points in evergreens; and he found that they absorbed less and transpired considerably less than other trees: hence, "the cedar of Libanus, and the ilex or evergreen oak, grafted on an English oak, and on a larch, were verdant all the Winter, though the leaves of the oak and larch decayed, and fell off as usual; the fact being, that evergreens live and thrive with very little nourishment."

Having proved that trees transpire large quantities of matter, our author next endeavoured to collect and examine it: he caused the branches and leaves to be enclosed in flasks and retorts; he placed a large sun-flower under the head of an alembic, and thus procured "what appeared to be pure water, very slightly tainted by vegetable matter; it seemed not to differ, though obtained from different plants." After some observations respecting the moisture and temperature of the earth, Dr. HALES proceeds with experiments to determine the force with which trees imbibe moisture, and here he obtained some striking results. He exposed the roots of a pear-tree, and cut off the end of one, half an inch diameter; the stump was cemented into the upper end of a tube twenty-six inches long, filled with water, and dipping at its lowest extremity into mercury. The root imbibed the water so vigorously, that in six minutes' time the mercury rose eight inches in the tube. This experiment was made in August. Another experiment, similarly contrived, in which a large branch of the root of an apple-tree was used, the diameter of its transverse section being three-fourths of an inch, caused the mercury to ascend five inches in half an hour. The oozing of air-bubbles from the cut surface interfered with the rise of the fluid in these tubes, but it was observed that the mercury rose highest when the sun was clear and warm; towards evening it subsided three or four inches, and rose again the next day. It also subsided during rain. This experiment was made in May. When we consider, says Dr. HALES, that the power thus required to raise mercury twelve inches, would raise water thirteen feet eight inches, we may form some idea of the power exerted by the growing vegetable.

Dr. HALES was one of the first who noticed the influence of cutting a ring of bark off the branch of a tree, (or *ringing*, as it is now technically called,) upon the growth of its fruit and leaves; but instead of attributing its effect to an accumulation of sap, the juice being prevented flowing downwards in the vessels of the bark, he refers it to a less quantity of sap arising, "whence it is better digested and prepared for the nourishment of the fruit;" he combats the notion of the sap *circulating* in trees, and imagines that it is often progressive at one time, and retrograde in another, in the same vessels.

Dr. HALES concludes his Vegetable Statics, with an account of some experiments to prove that a considerable quantity of air is inspired by plants, and with some observations on the growth of seeds and vegetables generally. By cementing a branch with its leaves, into a glass tube dipped into water, he observed the liquid rise in the tube, in consequence of the absorption of the confined air; and on putting a piece of the stem of a birch-tree under the receiver of an air-pump, he extracted abundance of air-bubbles from it during the exhaustion. He refers the first growth of a seed to the absorption of moisture, which swells it, and, as he thinks, protrudes nourishment into the radicle, which soon becomes capable of absorbing moisture from the soil; the root, he says, by expanding, carries the seed-lobes upwards with the plume, where they expand into leaves, which are of such importance to the tender plume, that it perishes on their removal; which renders it probable that they do the same office to the plume that the leaves adjoining to apples, quinces, and other fruits do to them; namely, draw the sap within reach of their attraction. As

the tree advances in stature the different lateral branches shoot out, "each lower order being longer than those immediately above them, not only on account of primogeniture, but also because, being inserted in larger parts of the trunk, and nearer the root, they have the advantage of being served with greater plenty of sap; hence arises the beautiful parabolical figure of trees. But when trees stand thick together in woods or groves, this their natural shape is altered, because the lower lateral branches being shaded, they can transpire little, and therefore drawing little nourishment, they perish; but the top branches being exposed to a free drying air, they transpire plentifully, and thereby drawing the sap to the top, they advance much in height; but if, when such a grove of tall trees is cut down, there be left here and there a single tree, that tree will then shoot out lateral branches; the leaves of which branches now transpiring freely, will attract plenty of sap, on which account the top, being deprived of its nourishment, usually dies."

Such are the leading objects of inquiry which engaged the attention of Dr. HALES; and, if we consider the little progress that had been previously made in pneumatic chemistry, we must allow that he much promoted that department of research: in his inquiries into the functions of vegetables he was at once original and acute, and laid the foundation of a very useful and curious series of investigations, which DUHAMEL, ANDREW KNIGHT, and others, have pursued with so much success. HALES entered into some collateral branches of investigation, the results of which are given in the *Philosophical Transactions*, and are collected in the second volume of his *Essays*; but they are not of such importance as to form any prominent feature in a general history of his discoveries.

When it is recollected that HALES wrote at the commencement of the last century, that there were then very few models of scientific composition extant that were worth copying, and that a pompous and obscure style of writing was prevalent among his experimental contemporaries, we cannot but admire the perspicuous and unadorned manner in which he details his facts and observations: he has all the merit that in this respect belongs to BOYLE, without his diffusiveness; and a pleasing vein of sound and unaffected morality accompanies his argument, and leads him, whilst endeavouring to unveil the mysteries of Nature, to direct our attention with becoming modesty to the penury of man's wisdom, when compared with the admirable adjustment of causes and effects discoverable in her lowliest works.

Contemporary with HALES was the celebrated HERMANN BOERHAAVE of Leyden, a man who laid medicine and chemistry under deep obligations; the former by his successful practice and happy method of instruction; the latter, by diligently experimenting in some of its most difficult departments. "He prosecuted chemistry," says Dr. JOHNSON, "with all the ardour of a philosopher whose industry was not to be wearied, and whose love of truth was too strong to suffer him to acquiesce in the report of others." BOERHAAVE's original chemical investigations were nearly of the same nature as those of HALES: he experimented upon the gaseous products afforded by a variety of vegetable and animal substances; he attributed the elasticity of air to its union with fire, and considered its ponderable matter as susceptible of chemical combinations. In disclosing

these views, he has certainly sketched an outline of one of the modern theories of combustion; but he went no further, and was not more successful than HALES, in discriminating between common air and the various gaseous products that resulted from some of his experiments. His writings are enumerated in chronological order, in the masterly sketch of his life, written by Dr. JOHNSON; "they have," says his biographer, "made all encomiums useless and vain, since no man can attentively peruse them without admiring the abilities and reverencing the virtues of the author." His only chemical work, entitled *Elementa Chemicæ*, was first published in 1732. It contains an useful essay on the History of the Science*.

§ IX.

THE names of BLACK and BERGMAN, with a host of others, either forgotten, or eclipsed by those eminent philosophers, occur in the division of our history at which we have now arrived, and which embraces its progress in the interval between the researches of HALES and those of PRIESTLEY. Chemistry now assumed a more important and interesting aspect: the facts already collected began to be digested and arranged, and active measures were taken to embody the scattered materials that presented themselves; to ascertain their relative value; to reject those which were unimportant or useless; and to select such as deserved to be dignified with the title of standard authorities. Dr. BLACK's researches possess a two-fold interest, for he not merely made important contributions to the facts of the science, but also established a new theory, connected with one of the most intricate of its subjects, heat.

Dr. JOSEPH BLACK was sprung from a Scottish family, transplanted first to Ireland and then to France, where he was born in 1728, on the banks of the Garonne. When twelve years of age, he was sent for edu-

* Boerhaave was born in December, 1668, at a village near Leyden. He died in September, 1738. He was an eminent ornament of medicine, as well as of chemical science. His oration upon resigning the office of Governor of the University of Leyden has been justly eulogized by Johnson. (*Life of Boerhaave*.) "He here declares in the strongest terms (says his eloquent biographer) in favour of experimental knowledge, and reflects with just severity upon those arrogant philosophers, who are too easily disgusted with the slow methods of obtaining true notions by frequent experiments, and who, possessed with too high an opinion of their own abilities, rather choose to consult their own imaginations than inquire into nature, and are better pleased with the charming amusement of forming hypotheses than the toilsome drudgery of making observations.

"The emptiness and uncertainty of all those systems, whether venerable for

their antiquity, or agreeable for their novelty, he has evidently shown; and not only declared, but proved, that we are entirely ignorant of the principles of things, and that all the knowledge we have is of such qualities alone as are discoverable by experience, or such as may be deduced from them by mathematical demonstration."

Boerhaave's contributions to physic were large and valuable. His *Elementa Chemicæ*, of which a good translation, with notes, was edited in 1753 by Dr. Shaw, he dedicated to his brother, who was intended for the medical profession, but went into the church; while Boerhaave, who originally studied divinity, relinquished it for physic and chemistry. Alluding to this circumstance, "Providence," says he, "has changed our views, and consigned you to religious duties, while I whose talents were unequal to higher objects, am humbly content with the profession of physic."

cation to Belfast, and afterwards to the University of Glasgow, where he entered upon the study of Physic, under the guidance of that bright ornament of medical science, Dr. WILLIAM CULLEN. In 1750, he removed to Edinburgh; four years afterwards, he took the degree of Doctor of Physic; and, in 1756, published his *Experiments on Magnesia, Quicklime, and some other alkaline substances, in the Physical and Literary Essays*. In the same year, CULLEN having removed to Edinburgh, BLACK returned to Glasgow, to fill the medical and chemical chair of that University, where he was received with open arms both by the classes and professors. In 1764, he brought his ideas respecting the combinations of heat with ponderable matter to maturity. Speculations upon this subject had occupied his mind during a considerable period, but the difficulties of the inquiry, and the time necessarily consumed in other professional avocations, had considerably interfered with the pursuit. In 1766, he was appointed to the chemical chair of Edinburgh, an office which he filled with such talent, industry, and perseverance, as not only drew an immense concourse of hearers to his class, but tended to confer upon chemistry a degree of popularity and importance, which has been greatly conducive to its promotion and extension. "His discourse," says his biographer, Professor ROBISON, "was so plain and perspicuous, his illustrations by experiment so apposite, that his sentiments on any subject never could be mistaken; and his instructions were so clear of all hypothesis or conjecture, that the hearer rested on his conclusions with a confidence scarcely exceeded in matters of his own experience*." In short, Dr. BLACK, in his professorial capacity, was entitled to every praise, and he contributed most essentially to the foundation and increase of the reputation which the University of Edinburgh has acquired and maintained. Nor was his private character at variance with his public excellence; he was mild, amiable, and fond of conversation, whether serious or sportive; and united to the highest philosophical attainments most of the elegant accomplishments of life. In his advanced age he often expressed a hope that he might not linger in protracted sickness, on account of the distress which, in such cases, is suffered by attending friends; and

* Dr. Black's character as a lecturer is given by his friend Professor Robison in the following terms:—"He endeavoured every year to render his courses more plain and familiar, and to illustrate them by a greater variety of examples in the way of experiments. No man could perform these more neatly and successfully. They were always ingeniously and judiciously contrived, clearly establishing the point in view, and never more than sufficed for this purpose. While he scorned the quackery of a showman, the simplicity, neatness, and elegance with which they were performed were truly admirable. Indeed, the *simplex munditiis* stamped everything that he did. I think it was the unperceived operation of this impression

that made Dr. Black's lectures such a treat to all his scholars. They were not only instructed, but (they knew not how) delighted; and without any effort to please, but solely by the natural emanation of a gentle and elegant mind, co-operating indeed with a most perspicuous exhibition of his sentiments, Dr. Black became a favourite lecturer; and many were induced, by the report of his students, to attend his courses, without having any particular relish for chemical knowledge, but merely in order to be pleased. This, however, contributed greatly to the extending the knowledge of Chemistry, and it became a fashionable part of the accomplishments of a gentleman."—*Preface*, p. LI.

his death, which happened in his seventy-first year, in November, 1799, is on this account the more remarkable. He was taking some milk and water, and having the cup in his hand, when the last stroke of his pulse was to be given, had set it upon his knee, and in this attitude expired without the smallest agitation.

The writings of BLACK, though few, are masterpieces of scientific composition. Newton was his model, and he was the first who transferred into chemistry the severe system of inductive logic, which marks the productions of that great master. "In no scientific inquiries, since the date of the *Principia* and *Optics*, do we find so great a proportion of pure ratiocination, founded upon the description of common facts, but leading to the most unexpected and important results, as in the two grand systems of BLACK." Averse to all hypothesis, and aware of the multitudinous facts upon which a theory that is to stand firm must be founded, Dr. BLACK was unwarrantably slow in the formal public disclosure of his researches. His tenets were fully and freely delivered to his pupils; but he rarely intruded upon the public as an author; and his achievements in the philosophy of heat are chiefly developed in his posthumous works. This silence, arising out of an overcautious modesty which marked all his proceedings, was not favourable to the reputation of Dr. BLACK. Faulty and incomplete copies of his lectures were circulated among his friends and admirers, which afterwards reached the hands of those who deserved another name, and by whom they were not very honourably employed.

When BLACK first entered the precincts of chemistry, there was a busy and acute controversy respecting the cause of causticity in earths and alkalis; it was supposed by STAHL that the conversion of limestone into quicklime depended upon its absorbing certain igneous particles; by MACQUER*, MEYER†, and others, the change was referred to an acrid

* Macquer was born at Paris in 1718, and died in 1784. He ranks among the most eminent scientific chemists of the early part of the eighteenth century; and though involved in the errors of the Phlogistic school, he has written with much good sense and perspicuity on a variety of chemical subjects. His most celebrated works are, the *Elemens de Chimie Théorique*, Paris, 1749; and *Elemens de Chimie Pratique*, Paris, 1751. He also published a Chemical Dictionary. The following is all his information respecting the property possessed by quicklime of rendering the alkalis caustic. After describing the process, he observes, "Le but de cette opération, est de réunir avec le sel alcali fixé ce que la chaux a de salin et d'âcre."—"On le combine avec la partie la plus âcre, la plus subtile, et la plus saline de la chaux."—"Nous n'entreprendrons point ici d'expliquer pourquoi le sel alcali, que l'on combine avec la chaux, acquiert une si grande causticité. Cette question nous paroît une des plus délicates et des plus difficiles à résoudre que nous

offre la Chimie. Elle tient à celle des propriétés alcalines de la chaux, et on ne peut guères espérer de la résoudre, que quand on aura acquis sur la nature de cette substance, beaucoup plus de lumières que nous n'en avons à présent."—*Elemens de Chimie Pratique*, pp. 179, 180.

† J. F. MEYER'S *Chemische versuche zur nähern erkenntniss des ungelöschten kalks; der elastischen und electrischen Materie, des allerreinsten feuerwesens, und der ursprünglichen allgemeinen saure*. Hanover, 1764. In this dissertation, though published subsequently to Black's essay, the causticity of the alkalis and lime is referred to the absorption of a principle which the author calls *Causiticum*, or *Acidum pingue*. Between the years 1760 and 1772, a great variety of dissertations were published in Germany upon this question, some in support of Black's doctrine, others in favour of Meyer's hypothetical absurdities. See GREN'S *Systematisches Handbuch der Gesammten Chemie*. Halle, 1794. § 437. —*Observ. Phys. Chem.*, 1722.

acid, contracted in the fire; by others, to nondescript saline particles. Dr. BLACK's notice appears to have been drawn to this inquiry, by the researches of HOFFMAN* concerning the nature of magnesia: he found that when that earth was obtained by adding a mild alkali to solution of Epsom salt, it effervesced upon the addition of an acid; but that if heated red-hot, it no longer effervesced, and moreover lost considerably in weight. The same fact applied equally to lime, and led him to believe, that that substance, instead of acquiring its acrimony by the absorption of something from the fire, became caustic by the loss or expulsion of one of its elements, in consequence of being heated. He then distilled some magnesia in a retort; but finding that, though it diminished considerably in weight, the only visible loss it sustained was a minute portion of water, he conceived the possibility of the escape of some gaseous matter; and, on mixing common magnesia and an acid in a proper phial, he collected a considerable quantity of a permanently elastic gaseous body: from chalk or limestone, and from the mild alkalis, he procured a similar gas, and he termed it *fixed air*.

In 1764, Dr. MACBRIDE, of Dublin, verified and extended these researches; he found that quicklime, after having been exposed to air, acquired the property of effervescing, and, consequently, fixed air must exist in the atmosphere†. He also explained the agency of lime as a manure, and introduced some important improvements into the art of tanning.

In 1765, Dr. BROWNRIGG threw out some curious hints upon the same subject: in a communication to the Royal Society, printed in the *Transactions* for that year, he remarks, "that a more intimate acquaintance with those noxious airs in mines, called *damps*, might lead to a discovery of that subtile principle of mineral waters, known by the name of their *spirit*; that the mephitic exhalations, termed *choak-damp*, he had found to be a fluid permanently elastic; and that, from various experiments, he had reason to conclude that it entered the waters of Pyrmont, Spa, and others, imparting to them that pungent taste, whence they are called *acidulæ*, and likewise that volatile principle on which their virtues chiefly depend;" and in 1760, Mr. LANE remarked the solubility of iron in water impregnated with fixed air.

I shall again have occasion to revert to the nature and properties of *fixed air*, which engaged much of the attention of PRIESTLEY, LAVOISIER, and other celebrated men, whose labours are yet to be noticed, consequently we may proceed to BLACK's researches on the subject of heat; researches which are more exclusively his own, and in which he has

* Hoffman was the most celebrated Chemical Physician of the age. He was born at Halle in Saxony, in 1660, and died in 1742. His writings, which are voluminous, are also valuable. In 1749, they were eked out by the Genevese booksellers into nine folio volumes. The following are his leading Essays in Chemistry: *Dissertationes de Generatione Salium*,—*De Natura Nitri*,—*De Cinabare Antimonii*,—*De Mirabili Sulphuris*

Antimonii fixati efficacia,—*De Mercurio et Medicamentis Mercurialibus*. *Observationum Physico-Chemicarum*—*Collectio*. Libri iii.

† MACBRIDE's *Experimental Essays*, 1764. The merit of this performance induced the University of Glasgow to bestow the degree of Doctor of Physic on the author. He was born in the county of Antrim in 1726, and died in 1778.

displayed that acuteness and originality which have given his name so high a rank in the annals of chemical science.

In speaking of the experiments of BOYLE, and of the investigations of the Florentine Academicians, two curious circumstances respecting the temperature of thawing ice and boiling water were noticed. It was stated that ice, during its liquifaction, retained an uniform temperature of 32° ; and that water, during its ordinary ebullition, never became hotter than 212° ; hence the use of those fixed points in the graduation of thermometers. We have now to examine the views which these phenomena suggested to Dr. BLACK, and the results that followed his inquiries into their causes and effects.

If a vessel of ice, of any very low temperature, be brought into a warm room, or placed near the fire, or over a small steadily burning lamp, a thermometer placed in it will gradually rise to 32° in the contact of the ice, and not higher, until the whole is melted. Then the temperature of the ice-cold water will begin to rise, and if the lamp be continued under the vessel, it will go on rising till it attains the temperature of 212° , when it again becomes stationary, and remains so during the whole evaporation. It follows, therefore, that heat is concerned in producing two series of changes: That its first effect is to thaw the ice without elevating the temperature; and that it then raises the thermometer till ebullition takes place, after which it converts the water into vapour, without elevating either its temperature or that of the vapour. Hence the following particular heads of inquiry suggested themselves:—

1. As to the *absorption* of heat during the conversion of solids into liquids, and of liquids into vapours.
2. As to the *evolution* of heat during the converse changes; namely, the condensation of vapours, and congelation of liquids.
3. As to the *quantity* of thermometric heat absorbed and evolved in these different cases.

The disappearance of thermometric or sensible heat alluded to in thawing ice, takes place in all corresponding cases of liquifaction; consequently, if a cold solid be mixed with a given weight of the same substance hot, and in a liquid state, the resulting temperature will not be the mean, as would have been the case if both portions had been in the liquid state, but will be considerably below it, a portion of the heat of the hotter body having been, as it were, consumed in liquifying the solid, without affecting its temperature. Thus equal parts of water at 212° and at 32° , give on mixture the mean temperature of 122° . But equal parts of water at 212° , and of snow at 32° , give upon mixture a temperature of 52° only, the excess of heat in this instance being concerned in *liquifaction*, not in elevation of temperature. Dr. BLACK considered the lost heat as equivalent to about 140° in the case of the liquifaction of ice; and among his experiments illustrative of this subject, the following may be selected as most relevant and simple:—Two similar globular glass vessels were filled with water, which in one was afterwards frozen; and in the other cooled as nearly as possible to the same point; they were then carried into a room of a temperature of 47° , there being no other difference between them than that the one contained ice and the other water. In half an hour the vessel of water had acquired the temperature of 40° ; but in the other it required ten hours and a half

to melt the ice, and raise the water to 40° . Now, as the access of heat was the same in both cases, and as this was at the rate of 7° in half an hour, it follows that in twenty-one half hours, (the time required to thaw the ice and elevate the temperature of the water to 40° ,) it would have received $7 \times 21 = 147^{\circ}$. The difference, therefore, between the increase of temperature in the ice and water vessels, with equal accessions of heat, is 140° , which will express the quantity of sensible heat rendered latent by the operation of liquifaction.

As heat is thus required to convert solids into liquids, it follows, that in cases of sudden liquifaction cold will ensue; hence its production, during the solution of many saline bodies, and hence, too, the explication of the theory of freezing mixtures. And as liquifaction is a cooling process, so congelation is a process in which heat is evolved. The freezing of large masses of water is actually a heating process to the circumjacent air. In the sudden crystallization of some saline solutions heat is evolved; and water, under certain circumstances, cooled to eight or ten degrees below its freezing point, suddenly rises to 32° upon congelation.

Having thus perspicuously disposed of the theory of congelation and liquifaction, Dr. BLACK turned his observation to the phenomena attendant on the formation of vapour, and there he was equally happy in his inquiries*.

When water is made to boil, the steam which rises from it is not hotter than the water itself, although there be a continuous influx of heat, which therefore must become *latent* in the steam; and consequently steam and other vapours may be regarded as compounds of liquids and heat.

To ascertain the thermometrical expression of the latent heat of

* "When we heat a large quantity of a fluid in a vessel, in the ordinary manner, by setting it on fire, we have an opportunity of observing some other phenomena which are very instructive. The fluid is gradually heated, and at last attains that temperature which it cannot pass without putting on the form of vapour. In these circumstances, we always observe that it is thrown into the violent agitation which we call boiling. This agitation continues as long as we throw in more heat, or any of the fluid remains, and its violence is proportional to the celerity with which the heat is supplied. Another peculiarity attends this boiling of fluids, which, when first observed, was thought very surprising. However long and violently we boil a fluid, we cannot make it in the least hotter than when it began to boil. The thermometer always points at the same degree, namely, the vaporific point of that fluid. Hence the vaporific point of fluids is often called their boiling point. When these facts and appearances were first observed, they seemed surprising,

and different opinions were formed with respect to the causes upon which they depend. Some thought that this agitation was occasioned by that part of the heat, which was more than the water was capable of receiving, and which forced its way through, so as to occasion the agitation of boiling; others, again, imagined that the agitation proceeded from air, which water is known to contain, and which is now expelled by the heat. Neither of these accounts, however, is just or satisfactory; the first is repugnant to all our experience in regard to heat: we have never observed it in the form of an expansive fluid like air; it pervades all bodies, and cannot be confined by any vessel, or any sort of matter; whereas, the elastic matter of boiling water, can be confined by external pressure, as is evident in the experiments made with Papin's digester."

This quotation from BLACK's *Lectures* (vol. i., p. 153) is inserted to show the state of the argument respecting the phenomena of ebullition previous to his researches.

steam, Dr. BLACK proceeded thus: The time required to elevate a quantity of water to its boiling point was carefully noted; the same heat was then continued till the whole had evaporated, and the time required also noted. Thus, supposing the accession of heat to have gone on above 212° , in the same ratio as below it, the temperature that the water would have acquired was estimated, whence it was inferred that the loss of sensible or thermometric heat amounted to more than 800° .

The vast evolution of heat during the condensation of steam now admitted of an explanation, and, on estimating the latent heat of steam, by condensing a given quantity in a given weight of water, it appeared to amount to between 900° and 1000° .

About the year 1774 it was observed by CULLEN* that a thermometer, moistened with spirit of wine or ether, sinks many degrees during the evaporation of those fluids: with ether, the thermometer may be made to fall from 60° to 0° . The cause of this is sufficiently explained by BLACK's theory; the ether and spirit readily pass into vapour, which requires a certain quantity of heat for its production: this is taken from the bodies it happens to be in contact with, as from the thermometer, or the hand; hence the cold perceived when these fluids are applied to the body, and the advantage which results from their application in cases of burns and inflammations. These circumstances led CULLEN to accelerate the evaporation of these fluids, by exposing them under the receiver of the air-pump: by placing a flask half full of ether in a tumbler of water, it was found that, during the process of exhaustion, the evaporation was so rapid from the ether in the flask, as to convert part of the surrounding water into ice†.

* "The chemistry of Stahl, as it was cultivated in Germany, and France, and other countries of Europe, scarcely aspired beyond the bounds within which it had been circumscribed by its original founder. A few important facts, indeed, were added, but they were either connected with medical preparations, or attracted attention solely as objects of curiosity. The great and tempting field of Philosophical Chemistry lay unexplored, when it was entered upon with ardour by Dr. Cullen, who first perceived its value, and whose genius and industry, had they not been turned into another channel, would, in all probability, have been crowned with the richest discoveries. But, though Dr. Cullen soon abandoned his chemical pursuits for those of medicine, he was fortunate enough to have initiated into the science a man whose discoveries formed an era in chemistry, and who first struck out a new and brilliant path, which was afterwards fully laid open, and traversed with so much eclat by the British philosophers who followed his career. This fortunate pupil of Dr. Cullen was Dr.

Joseph Black."—THOMSON, *History of the Royal Society*, p. 468.

Dr. Cullen's fame as a promoter of chemistry has been lost in his greater celebrity as a teacher of medicine. "Chemistry," says his biographer, Dr. Anderson, "which was, before his time, a most disgusting pursuit, was, by him, rendered a study so pleasing, so easy, and so attractive, that it is now pursued by numbers as an agreeable recreation, who, but for the lights that were thrown upon it by Cullen and his pupils, would never have thought of engaging in it at all."

Cullen was born in Lanarkshire, in 1712, and died at Edinburgh in 1790.

† Dr. Cullen's paper is published in the *Physical and Literary Essays and Observations*, Edinburgh, 1756, vol. ii. It contains the details of many interesting experiments upon the production of cold, and he considers the power of fluids in this respect as nearly according to the degree of volatility in each. "If to this," says he, "we join the consideration that the cold is made greater by whatever hastens the evaporation, and

The cause of the cold thus produced by evaporation now therefore became apparent, since no vapour can be in any instance formed without a proportionate absorption, or disappearance, of heat; and the theory of cooling by evaporation from surfaces, as in wine and water coolers composed of porous materials, and of cooling by the affusion of spirit of wine, ether, and other rapidly evaporating substances, became at once evident. LESLIE'S experiment on the production of ice by the evaporation of water *in vacuo*, and WOLLASTON'S *Cryophorus*, beautifully illustrate these views, but it would require much more extensive consideration than we can here afford, to trace all the bearings of the highly important investigations in which the name of BLACK is concerned. There is, however, one subject connected with them, upon which it would be improper not to offer one or two remarks: Dr. BLACK, in his published Letters, has said, "I have the pleasure of thinking, that the knowledge we have acquired concerning the nature of elastic vapour, in consequence of my fortunate observation of what happens in its formation and condensation, has contributed in no inconsiderable degree, to the public good, by *suggesting* to my friend Mr. WATT* of Birmingham, then of Glasgow, his improvements on this engine:" meaning the steam-engine, of which he is then speaking. We are not, however, to conclude from these lines that Dr. BLACK meant to assume any of the merit which exclusively and justly belongs to Mr. WATT; for in the context, he gives him all praise for the originality of his invention; and, in his private correspondence, recommends him particularly to assert, clearly and fully, his sole right to the honour of the improvements of the steam-engine; and, further, in a written testimonial given by Dr. BLACK to Mr. WATT, on the occasion of a trial at law in 1797, connected with a piracy of one of his inventions, after giving a brief account of it, he adds, "Mr. WATT was the sole inventor of the capital improvement and contrivance above-mentioned†."

particularly that the sinking of the thermometer is greater, as the air in which the experiment is made is warmer, if dry at the same time, I think we may now conclude that the cold produced is the effect of evaporation."

* The celebrated James Watt was born at Greenock, on the 19th of January, 1736; and died on the 25th of August, 1819, at Heathfield, near Birmingham, in the 84th year of his age.

† This may be the proper place to show in what way the views of Dr. BLACK'S *Theory of Latent Heat* are connected with the improvements of the steam-engine, a subject upon which I must necessarily be brief, as only in part belonging to the object of this history. The Marquess of Worcester is commonly regarded as the inventor of the steam-engine, but his claims are not well authenticated. It is true, that, among the Utopian schemes to be found in his *Century of Inventions*, there is a dark

description of a method of raising water by steam; but we can scarcely see how this was effected, nor are there any data recorded of the success of the contrivance. Be this as it may, he who barely and obscurely hints the possibility of an undertaking, cannot be regarded as forestalling him who successfully carries it into execution; and the first person who, upon decided evidence, constructed an engine for raising water by the alternate force and condensation of steam, was Captain Savary,—who also published an account of his invention in a small tract called the *Miner's Friend*. To enter into a description of this instrument would be irrelative to my present purpose; I, therefore, pass on to that of Newcomen, who, in 1705, obtained a patent for an improved steam-engine. It consisted of a boiler, having a cylinder placed upon it, in which was a solid plunger, connected by its rod with a beam and lifting-pump. The plunger

WATT's *capital improvement*, above alluded to, consisted chiefly in condensing in a separate vessel, and was adopted before he had any clear notion of Dr. BLACK's investigations; or at least the main experiments upon which this improvement hinged were previously undertaken.

was elevated by the elastic force of steam admitted from the boiler. The steam-cock being closed, a small stream of cold water was suffered to run into the cylinder, by which the steam was condensed; the pressure of the atmosphere then acting upon the surface of the plunger, forced it to the bottom of the cylinder, whence it was again raised by the re-admission of steam, and so on. In 1717, Mr. Henry Beighton became an improver of the steam-engine; he was probably the first who caused the steam-cock to be opened and shut by the machinery; for a man was obliged to attend Newcomen's engine for this express purpose. A few other improvements were made by different persons, but they did not affect the general action of the engine; the steam was alternately admitted into, and condensed in the main cylinder; and although defects in its power had been noticed, their cause was unknown until 1765, when, happily for the prosperity of the arts and manufactures of this country, the subject engaged the keen ingenuity of Mr. Watt. The model of a Newcomen's engine fell into his hands to be repaired, and in this he presently observed the immense loss of steam occasioned by its admission into the cylinder just cooled for condensation; indeed, he went so far as to ascertain, by experiment, that half the steam of the boiler was thus lost. For, having constructed a boiler which showed the quantity of steam expended at every stroke of the engine, he found that it many times exceeded that which was sufficient to fill the cylinder. But the circumstance that excited his greatest surprise was, that the injection water gained infinitely more heat than if a quantity of boiling water, equal to that required to form the steam, had been added to it. It was probably in this dilemma that he consulted Dr. Black; and the explanation of the difficulty will be obvious from the facts detailed in the text. To avail, himself, therefore, of the whole power of the steam, it became absolutely necessary to keep up the temperature of the cylinder constantly at the boiling point of water; this he was enabled to attain, by connecting with it

another vessel exhausted of air, and, immersed in cold water, into which, when communicated with the cylinder, the steam, being an elastic fluid, instantly rushes and is condensed; and, on closing its connexion with the cylinder, the steam again admitted there now operates with full force, and suffers no further condensation. To carry off the water from the second vessel, which he calls the *condenser*, and to perpetuate the vacuum, Mr. Watt attached to it a pump, by which both the air and condensed water are removed. The engine thus altered produced the same power as one of equal dimensions on Newcomen's plan, with rather less than one third the quantity of steam; hence was a considerable hindrance to the use of the engine materially diminished, namely, the expense of fuel.

But great as was this improvement, it forms a small part of the successful achievements of Mr. Watt in this department of mechanics; he amended the apparatus for boring the cylinders, and improved every part of the working gear of the engine; and he infinitely extended its applications and utility, by applying the power of steam to produce motion round an axis; but their enumeration would lead me out of the bounds of chemistry. I, therefore, hasten to the invention which may be said to have perfected the steam-engine. Steam had hitherto only been used to force the piston down,—it was returned by a weight attached to the other end of the beam. Mr. Watt, in 1782, constructed an engine in which steam was used to elevate as well as to depress the piston, an alternate vacuum being formed above and below it, by the condenser, as before. An engine upon this plan, executed at Mr. Watt's manufactory, at Soho, near Birmingham, was first employed at the Albion Mills, near Blackfriar's-bridge, London, in 1788.

An excellent sketch of the history of the steam-engine will be found in the *Edinburgh Review*, vol. xiii. p. 311, and some valuable additions to the biography of Watt and the history of his discoveries are contained in the *Eloge* of M. ARAGO.

It must be observed here, that Mr. WATT made a variety of curious investigations upon the subject of steam, and of the capacity of bodies for heat (a subject first inquired into by Dr. BLACK, in 1762), in themselves highly important: but these, and his other mechanical and chemical researches, have been obscured by the magnitude of his inventions and discoveries more immediately connected with the perfection of the steam-engine.

If the suspicion of jealousy, of want of candour, or of any deviation from the strictest veracity, could, by any possibility, attach to either of the philosophers whose labours we have been adverting to, it might be worth entering into such details as would more distinctly unfold their respective claims; as it is, however, I trust the short allusion made to the subject, while it places the assertions of the one in their proper light, will sufficiently vindicate the exalted merit and indisputable originality of the other.

To Mr. WATT's character, in relation to the public, and as a private individual, it is more than difficult to do justice, for the combined eloquence of the different writers who have attempted it has only feebly depicted the influence of his talents upon the state of society; and still less has it succeeded in the more difficult portraiture of the man, occupied in the ordinary duties of life, and in the intercourse of social converse. Such, at least, is my impression upon looking over the different biographical sketches that have lately appeared. I consider myself as highly fortunate in having occasionally enjoyed the society, and profited by the information of one who was so eminent a benefactor to his country. "He was a man," says Sir WALTER SCOTT, "whose genius discovered the means of multiplying our national resources to a degree, perhaps even beyond his own stupendous powers of calculation and combination; bringing the treasures of the abyss to the surface of the earth; giving the feeble arm of man the momentum of an Afrite; commanding manufactures to arise, as the rod of the Prophet produced water in the desert; affording the means of dispensing with that time and tide which wait for no man, and of sailing without that wind which defied the commands and threats of Xerxes himself. This potent commander of the elements,—this abridger of time and space,—this magician, whose cloudy machinery has produced a change on the world, the effects of which, extraordinary as they are, are perhaps only now beginning to be felt, was not only the most profound man of science, the most successful combiner of powers and calculator of numbers, as adapted to practical purposes; was not only one of the most generally well-informed, but one of the best and kindest of human beings. In his eighty-fourth year his attention was at every one's question, his information at every one's command." "No individual in his age," says another, and equally able writer, "possessed more varied and exact information. He had infinite quickness of apprehension, a prodigious memory, and a certain rectifying and methodizing power of understanding, which extracted something precious out of all that was presented to it. His stores of miscellaneous knowledge were immense, and yet, less astonishing than the command he had over them. His conversation had all the charms of familiarity, with all the substantial treasures of knowledge. With this philosophical

excellence of character, be it never forgotten that Mr. WATT conjoined the higher duties and more exalted attributes of sincere, but unaffected piety. Expressing his gratitude to Providence for that length of days and exemption from infirmity which rendered the evening of his life cheerful and serene, he yielded up his soul in the calmest tranquillity, and passed, without pang or struggle, from the bosom of his family to that of his God!"

§ X.

It is not perfectly in chronological order, to proceed in the present Section to the discoveries of Dr. PRIESTLEY*, and yet they are so numerous and important, that it will be difficult to continue the history of chemistry up to his time, without allusion to their objects and results. I shall, therefore, endeavour to give the reader some insight into the nature and bearings of his inquiries.

PRIESTLEY'S entire force was directed upon Pneumatic Chemistry. We have seen what may be termed the materials for the foundation of this branch of knowledge, in the works of MAYOW and HOOKE; it was pursued, as we have also found, with much diligence, but, unfortunately, in rather a desultory style, by HALES; PRIESTLEY directed his attention to it with a degree of activity and skill peculiarly his own; and, in the number of his discoveries, left his contemporaries far in the back-ground, while he certainly rivalled them in their interest and importance; and this is the more surprising, when we reflect that his philosophical studies seem generally to have been considered as subordinate to more severe and serious occupations. He first turned his attention to chemistry about 1768; he used to amuse himself with experiments on fixed air and artificial mineral waters, and one experiment, as he says, leading to another, he soon collected those materials which he laid before the Royal Society in 1772, under the title of *Observations on different Kinds of Air*. With what zeal and success he prosecuted this subject, will be seen in the sequel.

The apparatus which is now used in the chemistry of gaseous bodies, is almost entirely of PRIESTLEY'S invention. The water-trough, with its sliding shelves and moveable supports for inverted jars; the methods of subjecting animals and plants to the action of different kinds of air; the mercurio-pneumatic apparatus for collecting gases absorbable by water; the means of measuring and weighing gases, and of subjecting them to the action of electricity, are only a few of the contrivances for which we are principally indebted to PRIESTLEY; many others, employed by MAYOW and HALES, were by him perfected or improved.

In his earliest experiments on fixed air, and on air tainted by combustion and respiration, Dr. PRIESTLEY has announced many highly interesting and new facts; but the discovery which takes precedence of the others, and upon which his fame has been chiefly, though not quite justly, founded, is that of Oxygen Gas, or, as he termed it, Dephlogisticated Air. I say not quite justly, because its brilliancy and importance have been suffered to overshadow many of his other original investigations, of

* Born at Fieldhead, near Leeds, 1733; died in Pennsylvania, 1804.

which we hear but little, though their aggregate influence upon the subsequent progress of chemistry was most direct and important; but the fact is, that PRIESTLEY having opened, as it were, a new and rich mine in the science, found therein such abundance of treasure, that he was able to do little more than bring it to the surface, where it was soon pillaged and carried off.

Dephlogisticated Air was discovered by Dr. PRIESTLEY on the 1st of August, 1774; the method of experimenting which he adopted, consisted in exposing a quantity of *Red Precipitate of Mercury* to the action of the sun's rays concentrated by a burning lens; the red precipitate was contained in a small flask, filled up with quicksilver, and inverted in a basin of the same metal. "I presently found," he says, "that by means of this lens air was expelled from it very readily. Having got several times as much as the bulk of my materials, I admitted water to it, and found that it was not imbibed by it. But what surprised me more than I can well express, was, that a candle burned in this air with a remarkable vigorous flame, very much like that enlarged flame with which a candle burns in nitrous air exposed to iron or liver of sulphur; but, as I got nothing like this remarkable appearance from any kind of air besides this particular modification of nitrous air, and I knew no nitrous acid was used in the preparation of the *mercurius calcinatus*, I was utterly at a loss how to account for it*." Red Lead, and several other substances, among which is enumerated *Nitre*, are also shown by our author to afford oxygen at a red heat; and here we may revert to the sagacity displayed by HOOKE in his notions already quoted, respecting the constitution of that salt, and its nitro-aërial particles; and remind the reader how remarkably his surmises have been verified by PRIESTLEY; for, upon turning to those pages of the *Micrographia*, in which the theory of combustion is explained, we cannot but admire the penetration with which the presence of a body possessing the qualities of oxygen is anticipated, though the experimental demonstration of its existence was not achieved till the middle of the succeeding century. To MAYOW we might pay a similar tribute of applause; but, in canvassing the discoveries of LAVOISIER and his associates, a more favourable opportunity will offer of placing these matters in their true light.

The "nitrous air exposed to iron," alluded to in the preceding paragraph, is the gas now called Nitrous Oxide, which PRIESTLEY also discovered, though he but imperfectly investigated its properties.

The next remarkable circumstance adverted to by our author in

* The following paragraph, with which Dr. Priestley prefaces his account of the discovery of Dephlogisticated Air, presents a picture of his mind in regard to the origin of his own researches.

"The contents of this section will furnish a very striking illustration of the truth of a remark which I have more than once made in my philosophical writings, and which can hardly be too often repeated, as it tends greatly to encourage philosophical investigations; viz., that more is owing to what we call

chance, that is, philosophically speaking, to the observation of *events arising from unknown causes*, than to any proper design or preconceived *theory* in this business. This does not appear in the works of those who write *synthetically* upon these subjects, but would, I doubt not, appear very strikingly in those who are the most celebrated for their philosophical acumen, did they write *analytically* and ingenuously." (*Exp. and Obs.*, vol. ii., p. 103.)

respect to dephlogisticated air, is its action upon nitrous gas, mixed with which, "it occasioned a much more considerable diminution than atmospheric air;" and, as the fitness of air for respiration appeared connected with the absorption thus produced, it was inferred that it would support respiration, an inference which the Doctor soon verified by placing a mouse in a jar of the dephlogisticated air, in which it lived half an hour, though, by previous trials, he knew that it would only live a quarter of an hour in the same bulk of atmospheric air.

In the observations connected with these experiments, PRIESTLEY enters pretty much at length into the theory of the production of dephlogisticated air; but I shall not follow him into these views, as they are not very consistent with facts, nor even plausibly applied to them: he hints, however, at several useful applications of oxygen, and especially recommends it for the production of intense heat, by directing a small jet of it upon a piece of burning charcoal.

Among the many and ingenious investigations of this Philosopher, none have produced more pleasing subjects of inquiry than those relating to the influence of vegetation upon air contaminated by combustion, respiration, and the putrefaction of animal matter. Finding that air was not spoiled by the growth of a sprig of mint kept in it for some months, he thought it possible that the process of vegetation might restore the air injured by burning candles; and, accordingly, on the 17th of August, 1771, he put a sprig of mint into air in which a wax candle had burned out, and, on the 27th of the same month, found that another candle burned perfectly well in it; and then, to verify the conclusion, he divided the injured air into two separate portions, putting the plant into one of them, and merely leaving the other standing over water; he never failed to find that a candle would burn in the former, but not in the latter. "This restoration of air," says PRIESTLEY, "I found depended upon the vegetating state of the plant; for though I kept a great number of the fresh leaves of mint in a small quantity of air in which candles had burned out, and changed them frequently for a long space of time, I could perceive no melioration in the state of the air. This remarkable effect does not depend upon anything peculiar to *mint*, for I found a quantity of this kind of air to be perfectly restored by sprigs of *balm*." Groundsel, spinach, and some other plants, were used with like effect, to show that it did not depend upon aromatic effluvia. In Dr. PRIESTLEY's *Observations on Air infected with Animal Respiration and Putrefaction*, a multitude of other facts are adduced to demonstrate its renovation when exposed to growing vegetables, and he is thus led to the following general remarks upon the subject:—"These proofs of a partial restoration of air by plants in a state of vegetation, though in a confined and unnatural situation, cannot but render it highly probable, that the injury which is continually done to the atmosphere by the respiration of such a number of animals, and the putrefaction of such masses of both vegetable and animal matter, is, in part at least, repaired by the vegetable creation; and notwithstanding the prodigious mass of air that is corrupted daily by the above-mentioned causes, yet, if we consider the immense profusion of vegetables upon the face of the earth, growing in places suited to their nature, and, consequently, at full liberty to exert all their powers, both inhaling and

exhaling, it can hardly be thought but that it may be a sufficient counter-balance to it, and that the remedy is adequate to the evil*."

In the year 1778 Dr. PRIESTLEY resumed this investigation, and verified his main conclusions by new and satisfactory experiments; he found, however, that it was necessary for their success that the plants should be in a state of healthy and natural vegetation, and that all plants were not equally efficacious, some indeed appearing rather to deteriorate than improve the contaminated atmosphere. About this time, too, he made the capital discovery of the evolution of oxygen by aquatic plants, growing in water containing carbonic acid; that the presence of light was necessary to this change; that in sunshine it was most rapid; that it was in great measure independent of warmth; and, lastly, that the bladders of some kinds of sea-weed (*fucus vesiculosus*), often contained air purer than the atmosphere. The renovation of the air contained in water, requisite for the respiration of fishes, was thus accounted for; and the circumstance of fishes and most other aquatic animals being unable to live for any time in pure water, though exposed to air, satisfactorily explained.

By his contrivance of receiving gaseous fluids over quicksilver, PRIESTLEY was able to collect and examine a number of new æriform products, absorbable by water; and in these inquiries he was eminently successful. CAVENDISH, in endeavouring to get inflammable air from a mixture of copper and spirit of salt, obtained one that lost its elasticity on the contact of water. "I was exceedingly desirous," says PRIESTLEY, "to become acquainted with it, and therefore began by making the experiment in quicksilver, which I never failed to do in any case when I suspected that air might either be absorbed by water, or in any other manner affected by it: and, by this means, I presently got a much more distinct idea of the nature and effects of this curious solution." He then goes on to show that this singular gas is derived from the acid, that it is very absorbable by water, and that common Spirit of Salt is in fact an aqueous solution of it. His next discovery in this department was that of an alkaline air from a mixture of lime and sal-ammoniac; it also was absorbed by water forming "volatile spirit of sal-ammoniac, much stronger than that procured by any other means." He now thought that by adding the acid to the alkaline air, he might possibly produce a neutral air, but immediate condensation ensued, and sal-ammoniac was deposited. What is now termed Sulphurous Acid, (or by PRIESTLEY Vitriolic Acid Air,) he also discovered; he obtained it in various ways, but chiefly by heating mercury with oil of vitriol; he examined many of its combinations, and inquired into its action upon a variety of bodies†.

* PRIESTLEY on Air, vol. i. p. 93, 3rd edition, 1781.

† The notice of this discovery enables me, by the insertion of the following extract from his *History of Vitriolic Acid Air*, to show the candour and exactness with which he acknowledges the hints, assistance, and discoveries of others:—

"My first scheme was to endeavour to get the vitriolic acid in the form of

air, thinking that it would probably be easy to confine it by quicksilver, for, as to the nitrous acid, its affinity with quicksilver is so great that I despaired of being able to confine it to any purpose. I, therefore, wrote to my friend Mr. Lane to procure me a quantity of volatile vitriolic acid," &c. "Seeing Mr. Lane the winter following, he told me, that if I would only heat any oily or greasy

I have now enumerated the principal discoveries which PRIESTLEY may claim as original; and, in importance, they are second to none that had been previously made, and barely inferior to those that have adorned the later progress of chemistry. We can scarcely call him the founder of Pneumatic Chemistry, after perusing the works of HALES and BLACK; but he achieved more in that new department of the science than any of his predecessors or contemporaries; and though on some points anticipated, his claims to originality are on others quite unequivocal. He cannot be called the discoverer of Nitrous Gas, for it is noticed by MAYOW; yet he developed its principal properties, pointed out its useful eudiometrical applications, and showed many new modes of obtaining it. He has been stigmatized as a defender of the unintelligible system of phlogiston; and he did defend it with unpardonable pertinacity*; but when we reflect that equally erroneous theories have been as warmly espoused in our own

matter with oil of vitriol, I should certainly make the very thing I wanted, viz., the volatile or sulphureous vitriolic acid; and, accordingly I meant to have proceeded upon this hint, but was prevented from pursuing it by a variety of engagements.

"Some time after this I was in company with Lord Shelburne, at the seat of Mons. Trudaine, at Montigny, in France; where, with that generous and liberal spirit by which that nobleman is distinguished, he has a complete apparatus of philosophical instruments, with every other convenience and assistance for pursuing such philosophical inquiries as any of his numerous guests shall choose to entertain themselves with. In this agreeable retreat, I met with that eminent philosopher and chemist, Monsieur Montigni, Member of the Royal Academy of Sciences; and conversing with him upon the subject, he proposed our trying to convert oil of vitriol into vapour, by boiling it on a pan of charcoal in a cracked phial. This scheme not answering our purpose, he next proposed heating it together with oil of turpentine. According, we went to work upon it, and soon produced some kind of air, confined with quicksilver; but our recipient being overturned by the suddenness of the production of the air, we were not able to catch any more than the first produce, which was little else than the common air which had lodged on the surface of the liquor, and which appeared to be a little phlogisticated by its not being much affected by a mixture of nitrous air."

* Dr. Priestley's last publication is a tract, which appeared after his retirement to America, in 1800. It is entitled *The Doctrine of Phlogiston established, and*

that of the Composition of Water refuted.

It contains a variety of miscellaneous observations on the phlogistic and antiphlogistic theories, but it would be useless to follow the author into his unsubstantial speculations on these subjects. He has, however, thrown out some important considerations relating to his claims of originality as the discoverer of dephlogisticated air. The following paragraph appears of sufficient interest to be transcribed:—"Now that I am on the subject of the *right of discoveries*, I will, as the Spaniards say, leave no ink of this kind in my inkhorn; hoping it will be the last time that I shall have any occasion to trouble the public about it. M. Lavoisier says (*Elements of Chemistry, English translation*, p. 36), 'this species of air (meaning dephlogisticated) was discovered almost at the same time by Mr. Priestley, Mr. Scheele, and myself.' The case was this:—Having made the discovery some time before I was in Paris in 1774, I mentioned it at the table of M. Lavoisier, when most of the philosophical people in the city were present; saying, that it was a kind of air in which a candle burned much better than in common air, but I had not then given it any name. At this all the company, and M. and Madame Lavoisier as much as any, expressed great surprise; I told them I had gotten it from *precipitate per se*, and also from *red lead*. Speaking French very imperfectly, and being little acquainted with the terms of chemistry, I said *plomb rouge*, which was not understood till M. Macquer said, 'I must mean *minium*.' Mr. Scheele's discovery was certainly independent of mine, though I believe not made quite so early." P. 88.

days by men who in no respect are to be considered as inferior to our author, we must not impeach his discernment upon so flimsy an accusation. When we consider his numerous, and as it were, incompatible occupations; and remember the many channels into which his exertions were occasionally directed, we presently detect the source of that wavering of opinion and unsteadiness of research which his philosophical pursuits display. His experiments were almost always submitted to the public in a crude and undigested form, for he had no time to build them into theories, or to concoct them into generalizations; and it is perhaps as well that he had not, for the bent of his mind was evidently such as to shine in experiment rather than argument.

The constitution of the atmosphere was one of the many inquiries which engaged PRIESTLEY's diligence*. In 1772, Dr. RUTHERFORD demonstrated the existence of a peculiar elastic fluid in atmospheric air, differing from fixed or mephitic air, and yet, like it, extinguishing flame, and unfit for respiration†. This component part of the atmosphere was, by PRIESTLEY, called Phlogisticated Air; and he showed that when mixed with nitrous gas, it suffered no diminution; but, on the contrary, that dephlogisticated air, on the same admixture in due proportions, was almost entirely absorbed over water; hence the method before noticed which he introduced, of ascertaining what was termed the goodness of atmospheric air, by the degree of absorption exhibited upon a certain admixture of nitrous gas, over water.

It was for his various discoveries, and more especially those relating to the physiology of vegetation, that the Council of the Royal Society honoured Dr. PRIESTLEY by the presentation of Sir GODFREY COPLEY's medal, on the 30th of November, 1783‡.

* The ancients appear to have regarded air as an ultimate principle of matter. Thus Lucretius,—

Aera nunc igitur dicam, quid corpore toto
Innumerabiliter privis mutatur in horas:
Semper enim, quodquomque fluit de rebus, id omne
Aeris in magnum fertur mare, qui nisi contra
Corpora retribuat rebus, recreetque fluentis,
Omnia jam resoluta forent, et in aera versa,
Haud igitur cessat gigni de rebus, et in res
Recidere assidue, quoniam fluere omnia constat.

De Rerum Natura, Lib. V. v. 274.

† "Sed Aer salubris et purus, non modo respiratione animali ex parte fit mephiticus, sed et aliam indolis suæ mutationem inde patitur. Postquam enim omnis aer mephiticus ex eo, ope lixivii caustici secretus et abductus fuerit, qui tamen restat nullo modo salubrior inde evadit, nam quamvis nullam ex aqua calcis præcipationem faciet, haud minus quam antea, flammam et vitam extinguit."

‡ Sir Godfrey Copley originally bequeathed five guineas to be given at each anniversary meeting of the Royal Society, by the determination of the President and Council, to the person who had been the author of the best paper of

experimental observation for the year past. In process of time, this pecuniary reward, which could never be an important consideration to a man of enlarged and philosophical mind, however narrow his circumstances might be, was changed into the more liberal form of a gold medal, in which form it is become a truly honourable mark of distinction, and a just and laudable object of ambition. It was, no doubt, always usual with the Presidents, on the delivery of the medal, to pay some compliment to the gentleman on whom it was bestowed; but the custom of making a set speech on the occasion, and of entering into the history of that part of philosophy to which the experiment related, was first introduced by Mr. Martin Folkes. The discourses, however, which he and his successors delivered, were very short, and were only inserted in the minute-books of the Society; none of them had ever been printed before Sir John Pringle was raised to the chair of the Society.—CHALMERS's *Biographical Dictionary*.—*Life of Pringle*.

Sir JOHN PRINGLE, who was then President, delivered on this occasion an appropriate discourse upon the different kinds of air, in which, after expatiating upon the discoveries of his predecessors, he points out the especial merits of PRIESTLEY's investigations. In allusion to the purification of a tainted atmosphere by the growth of plants, the President has thus expressed himself:—

“From these discoveries we are assured that no vegetable grows in vain; but that, from the oak of the forest to the grass of the field, every individual plant is serviceable to mankind; if not always distinguished by some private virtue, yet making a part of the whole which cleanses and purifies our atmosphere. In this the fragrant rose and deadly nightshade co-operate; nor is the herbage, nor the woods that flourish in the most remote and unpeopled regions, unprofitable to us, nor we to them, considering how constantly the winds convey to them our vitiated air, for our relief and their nourishment. And if ever these salutary gales rise to storms and hurricanes, let us still trace and revere the ways of a beneficent Being, who not fortuitously, but with design, not in wrath, but in mercy, thus shakes the water and the air together, to bury in the deep those putrid and pestilential effluvia which the vegetables on the face of the earth had been insufficient to consume*.”

The chemistry of gaseous bodies, in consequence chiefly of PRIESTLEY's investigations, now became a main branch of the science, and some of his most eminent contemporaries were equally diligent with himself in its promotion and elucidation. Among others, BERGMAN and his friend and pupil, SCHEELE, may be ranked among its successful followers; and CAVENDISH lent it his powerful aid; but I have thought it better to confine myself to the abstract view of such of PRIESTLEY's discoveries as may

* Dr. Franklin, in a letter upon the subject of these discoveries to Dr. Priestley, has expressed himself as follows:—

“That the vegetable creation should restore the air which is spoiled by the animal part of it looks like a rational system, and seems to be of a piece with the rest. Thus, fire purifies water all the world over. It purifies it by distillation when it raises it in vapour, and lets it fall in rain; and further still by filtration, when keeping it fluid, it suffers that rain to percolate the earth. We knew before that putrid animal substances were converted into sweet vegetables when mixed with the earth and applied as manure; and now, it seems that the same putrid substances, mixed with the air, have a similar effect. The strong thriving state of your mint, in putrid air, seems to show that the air is mended by taking something from it, and not by adding to it. I hope this will give some check to the rage of destroying trees that grow near houses, which has accompanied our late improve-

ments in gardening, from an opinion of their being unwholesome. I am certain from long observation, that there is nothing unhealthy in the air of woods; for we Americans have everywhere our country habitations in the midst of woods, and no people on earth enjoy better health, or are more prolific.”—*Phil. Trans.* 1772, page 199.

Notwithstanding these researches, which have exposed some very curious facts relative to the chemical physiology of plants, it must be confessed that the causes of the renovation and equality of our atmosphere are yet by no means ascertained; for, although some growing vegetables do, under certain circumstances, purify the air (by the absorption of carbon and the evolution of oxygen), yet, when in a state of decay, they invariably add to its contamination; and a general view of the subject would lead us to [conclude that vegetables produce little effect upon the general constitution of the atmosphere.

be strictly termed his own, than to blend them with the achievements of other philosophers, who experimented with distinct views, though occasionally treading in his footsteps.

§ XI.

BERGMAN, of Sweden, was born in the year 1735, and died in 1784, in consequence of too intense application to his studies: he was not only a diligent traveller in the beaten paths of chemistry, but he searched the depths, and ascended the heights of the science; his life was short, but as he neither lost nor misemployed time, his activity compensated for the brevity of his days; he not only opened a new mine in his favourite science, but examined its treasures and scattered its riches, for BERGMAN may be said to have almost invented the art of chemical analysis.

In his *Prefatory Essay on the Investigation of Truth*, this author has depicted his feelings upon the subject of experimental science in perspicuous and unaffected terms; and a mind so directed could not but be successful in its exploits, when we remember that even in his days there were few willing entirely to throw off the presumption of scholastic philosophy. "A tendency," he says, "to Cartesianism still exists, and upon attentive consideration it will not appear wonderful that the human mind should delight to indulge in this method; for, on the one hand, the way of experiments is expensive, troublesome, and tedious; all minds, therefore, are not capable of enduring it; many are without the proper instruments, others want the necessary dexterity; but the most universal defect is that of patience and perseverance, so that if the experiment does not at once succeed it is abandoned in disgust. Man, in his ordinary state, seems by nature prone to indolence. On the other hand, the contemplative method favours the desire of knowledge; by pretending to unlock the secrets of nature with ease and expedition, it soothes the natural rage of explaining all things; and by supposing everything accessible to the human intellect, administers pleasing flattery to vanity and arrogance."

It is upon the talents of BERGMAN, as an analyst, that I propose to dwell; it is there that he was pre-eminently original and successful, and upon that foundation his character as a chemist may safely be built.

The use of tests, for the discovery of certain substances held in aqueous and other solutions, is first particularly dwelt upon by BOYLE, and he was sometimes very fortunate in their contrivance and applications. He noticed the conversion of certain vegetable blues to red by acids, and to green by alkalis; the cloudiness produced by common salt in solution of silver, its discoloration by liver of sulphur, and several other circumstances connected with the detection of certain principles by chemical re-agents. In 1667 DU CLOS undertook an examination of the waters of France; and in 1686 HIERNE published some clever experiments upon the same subject in Sweden. In these writers the use of galls for the detection of iron is alluded to, and the necessity pointed out of examining the residuary product of evaporation. In 1726 and 1729 BOULDUCE used spirit of wine to precipitate certain saline bodies insoluble in that menstruum. In 1755 VENEL pointed out the existence of fixed

air in the waters of Seltzer, Spa, and Pyrmont; LANE, in 1769*, showed the method of imitating chalybeate springs; and in 1772 Dr. PRIESTLEY published directions for saturating water with fixed air.

BERGMAN, in his *Essay on Mineral Waters*, after adverting to a variety of circumstances relating to their general characters and sources, proceeds to point out, in the seventh section, the principal re-agents and precipitants useful in their examination, and to describe the nature of their changes and indications, with useful precision, in the following order:—

A. Infusion of litmus, or turnsole, is so delicate a test for the acids, that a single grain of sulphuric acid reddens 408 cubic inches of the blue tincture. Paper, dipped in this tincture, and reddened by distilled vinegar, has its blue colour restored by alkalis; but the tincture is more sensible than the paper, for the latter is not reddened by ærial acid (fixed air); yet one part of water, saturated with ærial acid, renders fifty parts of the infusion red.

B. Tincture of Brazil-wood becomes blue by alkalis, and is sensible to less than one grain of crystallized soda in 4000 of water.

C. Turmeric, either on paper, or in watery tincture, is a good, but less sensible, test for alkalis, which render it brown.

D. Tincture of galls discovers iron by a purple or black cloud.

E. Prussiate of Potash produces a blue tinge in water containing a minute portion of iron; it also precipitates other metals; copper, brown; manganese, white.

F. Sulphuric acid forms a white precipitate in all solutions containing baryta. If it produces bubbles, it indicates some combination of ærial acid. Nitric acid is highly useful for showing the presence of sulphur, which it precipitates from hepatic waters.

G. Oxalic acid detects the minutest quantity of lime, by producing a white cloud, either immediately or after some hours. This test shows that scarcely any water is free from lime; and the purest, within twenty-four hours, deposits a portion of oxalate of lime, although sometimes so sparingly as to escape observation, unless lines be drawn on the bottom of the vessel with a glass rod, in the direction of which the precipitate attaches itself.

H. Aërated fixed alkali throws down the metals and earths; if the substance be easily soluble in ærial acid, the caustic alkali may be used.

I. Aërated volatile alkali also throws down earths and metals, and is an excellent test for the presence of copper, which it indicates by a blue colour, more or less intense according to the quantity of alkali added.

K. Lime-water detects ærial acid, by a precipitate of aërated lime.

L. Muriate of baryta forms an insoluble white precipitate in water containing any soluble vitriolic salt; twelve grains of crystallized Glauber's salt, dissolved in a kanne of distilled water (about three quarts), immediately exhibits white striæ on the application of this test. Even one grain in the kanne exhibits a white cloud after some hours, and as it only contains 0.26 grains of

* Mr. Lane was the first who ascertained the solubility of iron in water impregnated with fixed air.—*Phil. Trans.* 1769. "By this means," says Sir John Pringle, in his discourse on the different kinds of air, delivered at the anniversary meeting of the Royal Society, November 30, 1773, "the nature of the metallic

principle in mineral waters was clearly explained, and the whole analysis of those celebrated fountains, so often attempted by chemists and others, and still eluding their laboured researches, was thus, in the most simple manner, brought to light."

sulphuric acid, we may judge of the nicety of this precipitant, which even exceeds turnsole itself in sensibility. M. Muriate of lime may be used for the detection of fixed alkali, but it is an ambiguous test, because, if sulphate of magnesia be present, it produces gypsum. N. Solution of alum is also of little use, though occasionally employed as a test for alkalis. O. Nitrate of silver is a certain and delicate indicator of muriatic acid and its combinations. A grain of common salt, in a kanne of water, is instantly rendered evident by white streaks. Under some circumstances it may also form a precipitate with sulphuric acid, but sulphate of silver is much more soluble than Muriate; thus, no visible turbidness arises, unless the kanne of water contains ninety-eight grains of Glauber's salt, or twenty five of vitriolic acid. The presence of hepatic air renders the precipitate of silver more or less brown. Alkalis, lime, and magnesia, also precipitate nitrate of silver. P. Nitrate of mercury is a prevaricating test, but very sensible to a variety of substances that may exist in mineral waters. As BERGMAN has not pointed out any particular application, in which this salt is essential, it will not be necessary to follow up his remarks on it, though in other respects important. Q. Corrosive sublimate; R. Acetate of lead; S. Sulphate of iron; and T. White arsenic are enumerated, but their utility is dubious, and the observations upon them of little value to the analyst. U. Spirituous solution of soap is useful in giving general indications of the purity of water, which, if pure, scarcely renders it opalescent; but, if abounding in foreign materials, or *hard*, and unfit for washing, it produces more or less opacity or precipitation. X. Liver of sulphur is affected by so many causes, that it may be dispensed with in the examination of waters. Y. Alcohol throws down such salts as it cannot dissolve, especially the sulphates. It dissolves many muriates and nitrates.

I have thus enumerated the tests recommended by BERGMAN, and given an abridged account of his remarks upon them, for the purpose of showing the progress which, under his assistance, was made in analytical chemistry: it is true that of many of these re-agents and of their applications he was not the original inventor; but he was the first who showed the real value and limits of the indications which they afford; an effort of no common sagacity, when we revert to the state of chemistry in his time.

Proceeding with the analysis of mineral waters, BERGMAN next adverts to the gaseous contents, which may be expelled by heating a given portion of the water in a retort, the beak of which is plunged into the mercurio-pneumatic apparatus, and the gas secured in the usual way. It commonly consists of pure air and ærial acid; the latter may be absorbed by lime-water. The presence of hepatic air is easily recognised by its odour. The remaining water is directed to be evaporated to dryness, and the residue weighed and digested in pure alcohol; the residue, insoluble in alcohol, is then to be shaken with eight parts of cold water; and finally, the matters which resist the action of alcohol and cold water are to be boiled in four or five hundred parts of distilled water, and the solution filtered. The ultimate residuum generally contains iron and carbonate of lime, or perhaps of magnesia, previously suspended by

carbonic acid; it may be in a few instances argillaceous or silicious, and perhaps contains manganese, and directions are given at length for its separate analysis, as well as that of the aqueous and alcoholic solutions. It is here that BERGMAN displays an ingenuity and accuracy then new to chemical science, for, in measuring his merits by a true estimate, we must go back to the state of chemistry at his time, and divest ourselves of its modern perfections and refinements; then the peculiar and genuine character of his researches will become prominent.

Having, in the paper of which the above is an outline, described the general principles of the analysis of mineral waters, BERGMAN proceeds, in several following essays, to apply them to individual analyses, and his dissertations on the waters and acidulous spring of Upsal, on sea-water, and on the artificial preparation of hot and cold medicated waters, each exhibit proofs of his skill as an analyst, and accuracy as an experimenter; but, although these and his other detached essays are excellent in their way, we must here pass them by, in order to examine such of his contributions as tended to the general improvement and extension of chemical science; among these, his luminous dissertation on chemical attraction*, already adverted to, is pre-eminent; and the twenty-fourth essay in the second volume of his *Opuscula*, entitled *De Minerarum Docimasia Humida* (on the Art of Assaying in the Humid Way), must be considered as the parent source of that branch of analytical chemistry so successfully followed up, though upon a limited scale, by SCHEELÉ, and in the improvement and extension of which KLAPROTH passed his long and laborious life.

It must be premised that the assay or analysis of minerals had, with the exception of the experiments of MARGRAAF†, hitherto been confined to certain operations effected by the aid of fire, in which, except in

* *De Precipitatis Metallicis.*

† Among those whose names became eminent in the history of chemical science during the first half of the eighteenth century, Margraaf is entitled to particular mention. He was born at Berlin, in 1709, where he died in 1782. He was a pupil of the once celebrated Neumann, a man whose works are now not much thought of, but who did considerable service to the chemistry of his day. Caspar Neumann was born at Züllichau, in Prussia, in 1682; and in 1705 we find him enjoying the patronage of the King of Prussia, by whom he was sent to complete his studies at the university of Halle. In 1711 he became a pupil of Boerhaave, and shortly after visited England, whence he accompanied George I. to Hanover, in 1716. In 1723 he became Professor of Practical Chemistry in the Royal College of Berlin, where he died in 1737. His works consist chiefly in dissertations on various subjects of chemical inquiry, published in the *Transactions of the Royal Society*,

and in the *Miscellanea Berolinensia*. His Lectures were not printed till after his death, and proved a valuable magazine of chemical knowledge. "The author," says Dr. Lewis, who edited his works, "biassed by no theory, and attached to no opinions, has inquired by experiment into the proportions and uses of the most considerable natural and artificial productions, and the preparations of the principal commodities which depend on chemistry, and seems to have candidly and without reserve communicated all he discovered." In 1733, Margraaf pursued chemistry under Juncker, at Halle, and, having returned to Berlin, in 1738, we find several of his contributions in the *Transactions of the Scientific Society*, of that capital. Subsequent to that period his works were collected and published at Paris in 1762. They contain a great body of information, at that time novel and important, but they are chiefly entitled to notice as furnishing specimens of the art of analysis.

common and obvious cases, their nature was rather guessed at than demonstrated. This art had its origin in the sixteenth century; and in 1576 the celebrated work of AGRICOLA brought before the public all that was important in relation to it, describing the instruments and processes with scrupulous and minute accuracy, and illustrating them by a curious collection of cuts. AGRICOLA was succeeded by LAZARUS ERCKERN, whose work on the docimastic art is much eulogized by BOERHAAVE. In the above-named essay BERGMAN points out the fallacies and imperfections to which igneous analysis is liable, and dwells upon the advantage of operating in the humid way, that is, by solvents and precipitants. He then proceeds to separate examinations of various metallic ores, as illustrations of his new method. Many of the conclusions and reasonings contained in this essay are founded upon the details of the preceding one on Metallic Precipitates. "He," says our author, "who first saw the corrosion of a metal by a limpid liquid, who beheld the opaque and ponderous body gradually disappear, and become a part of a transparent and apparently homogeneous fluid, and who saw the same metal re-appear upon the addition of a proper precipitant, must have been infinitely surprised, and struck with admiration of the occult powers of nature. But because we are accustomed to these phenomena, we neglect inquiring into their causes, though of the utmost importance, as forming the entire basis of practical chemistry. Such phenomena are so varied and intricate that volumes would be insufficient for their complete discussion; so that I propose to limit my observations to the separation of metals from acids, and to the particular consideration of *the weights of the precipitates*." Then, after a luminous summary of the general phenomena of the solution of metals, he advances a series of facts relating to their precipitation; he shows that the caustic fixed alkalis occasion precipitates of the *calces*, but loaded with water, by which their weight is much increased: that carbonated alkali precipitates carbonated oxides by double decomposition: that certain acids, which form insoluble compounds with metals, throw them down from their soluble compounds: that certain salts act in the same way by double elective attraction; and that in some cases triple combinations ensue, as when platinum is precipitated by sal ammoniac. He then adverts to the decomposition of one metallic salt by another, even where the acid is the same in both. Thus, sulphate of iron and muriate of tin decompose muriate of gold. The metals also precipitate one another after a certain order, which is the same in all acid solvents, and effected by double elective attraction, "for the metal to be precipitated exists in the solution in a calcined state, but, being reduced by the phlogiston of the precipitant, falls to the bottom; while the precipitant, being calcined, becomes soluble. Although," he says, "many anomalous circumstances occur in this matter, the order is constant and never inverted." The fifth section of this paper explains the use of tests for discriminating the metals, pointing out the colours of metallic precipitates. "Gold and platinum are only in part separated from acids by the alkalis. Nitrate of silver affords a brown precipitate with caustic, and a white with aerated soda and with muriatic acid. Solution of nitrate of mercury gives a red precipitate with carbonated, and a yellowish, or orange, with caustic alkali. The latter is black, if the solution be prepared

without heat. Nitrate of lead is precipitated, white by caustic alkali, an excess of which re-dissolves the precipitate. Nitrate of copper gives a bright-green compound with aërated, and brown with phlogisticated alkali (prussiate of potash). Iron is thrown down green by aërated alkali, and the precipitate, on exsiccation, becomes brownish-yellow. Tin gives a white cloud with all the alkalis; bismuth, white with water and alkalis; nickel, greenish-white with alkalis and prussiate of potash; zinc and antimony white with all alkalis."

Such is a short abstract of the contents of this section, which, although obscured by the language of the old school, and therefore scarcely, perhaps, intelligible to the chemical student of the present day, abounds in useful and perspicuous details: it is followed by the concluding section, containing a table of the relative weights of precipitates, procured in different ways, from a solution of one hundred parts of metals; and, as BERGMAN observes, "this table, upon proper examination, reveals many mysteries." It seems to have been the general opinion at this period, that the relative weights of precipitates were in all cases the same; that is, one hundred parts of lead, for instance, dissolved by nitric acid, and precipitated by caustic, aërated, and phlogisticated alkali, and by sulphuric acid, would furnish an equal weight of precipitate in each individual instance. Our author here shows the fallacy of this opinion, and demonstrates the difference of weights to depend upon the different proportions of the precipitant contained in the precipitate, and upon the occasional retention of a portion of the solvent. The list of precipitates annexed to this paper will disclose, to the attentive observer, principles analogous to those exhibited by the tables of RICHTER, and upon which one of the main pillars of the theory of definite proportionals may be said to rest.

BERGMAN's essay on fixed air, or as he calls it, *aërial acid*, is the last of which I shall make any particular mention. His chief experiments on this subject were probably made about the year 1770. The dissertation I am now quoting was read, in 1774, before the Royal Society of Sciences at Upsal, and is printed in their *Transactions* for 1775. After describing the several methods of obtaining fixed air by the action of acids upon carbonates, by submitting them to a red heat, and by fermentation, he proceeds to define the meaning of the word *acid*, in order to show that fixed air belongs to that class of bodies; that it is soluble in water, that it has a sour taste, reddens turnsole, and unites to and forms crystallizable compounds with alkalis, destroying at the same time their causticity. He detected this acid in the *marmor metallicum* of CRONSTEDT (carbonate of baryta), and observed the rapidity with which baryta-water absorbs carbonic acid from the air, forming an effervescent precipitate. Speaking of the action of carbonic acid upon lime, he gives a masterly sketch of the principal facts relating to the composition and decomposition of the carbonate of lime: he shows the solubility of calcareous spar in water impregnated with fixed air, and its subsequent deposition, often in small crystals; and the same property is also proved to belong to magnesia. BERGMAN then goes on to discuss the elective attractions of fixed air, of which he gives the following table:—

He says it appears to be the weakest acid known, for it is expelled not only by vinegar, but by the phlogisticated acids of nitre and of vitriol (nitrous and sulphurous acids); yet he observes that acetate of lead as decomposed by carbonic acid, which appears an anomaly, and suggests a question which he leaves undecided till experiment shall have enabled him to explain it. The acid properties of fixed air are next dwelt upon, and the probability of its acidity resulting from foreign matter negatived; for when "rightly depurated, though extricated by the most different means from the most different materials, whether by fire or by solution, it is nevertheless always the same, and always acid. I conclude, therefore, with all the certainty attainable in physics, that acidity is a property essential to that elastic fluid." From the imperfection of apparatus, BERGMAN erred a good deal in calculating the specific gravity of fixed air; he, however, proved it heavier than atmospheric air, and thence accounts for its lodging in low situations, as in pits and grotts: it is also shown to extinguish flame.

AERIAL ACID.

Pure terra ponderosa.
 — lime.
 — fixed vegetable alkali.
 — fixed mineral alkali.
 — magnesia.
 — volatile alkali.
 — Zinc.
 — Manganese
 — Iron.

The essays which I have now quoted, and which may be taken as a fair sample of his method of investigation, exhibit BERGMAN in the light of a true philosopher, employing hypothesis as the precursor, and not the substitute of experiment; countenancing no theory but such as admits of rigid demonstration; advancing no favourite doctrines nor hasty speculations; but always the candid narrator of facts. As the repeater of the experiments of others, he measures and weighs their conclusions, and assigns them their proper place in the history of science. When in the character of an original inquirer, he kindles the torch of experiment, and never advances beyond the boundary of its light. He seems profoundly to have admired Newton, and to have endeavoured to transfuse his methods of investigation into chemistry. "That illustrious personage," he says, "having solicitously accumulated facts, examined them with accuracy, and compared them with acuteness; from effects he advances to causes, and thence deduces the laws of the creation. His progress, though slow, is certain; and his method, though tedious, is continually unveiling the mysteries of nature. An edifice thus constructed acquires firmness by elevation, for its foundations are solid and permanent."

There is more method in BERGMAN than in any antecedent chemical writer; his researches appear always to have been made with an object in view; and there is an unity of design in his philosophical papers, which pleasingly distinguishes them from the undigested chaos of experiments and observations which we are obliged to wade through in many preceding authors.

BERGMAN had many celebrated successors in analytical chemistry, as applied to mineral substances; among these, KLAPROTH and VAUQUELIN have especially contributed to the progress of this branch of the science. MARTIN HENRY KLAPROTH, was born at Wernigerode, in Prussia, on the 1st of December, 1743; and died at Berlin on the 1st of January, 1817.

He was an excellent man, and a diligent and accurate analyst: he was a pupil of ROSE of Berlin, who died in 1771. He published a variety of important papers in periodical works; and in 1795 collected them, under the title of *Beiträge zur Chemischer Kenntniss der Mineralkörper*, (contributions towards the chemical knowledge of mineral substances.) Of this work, consisting of six volumes, the last was published in 1815; it contains not less than two hundred and seven essays*.

VAUQUELIN, who died, at an advanced age in Paris, in 1829, was originally a peasant boy of Normandy. He was employed in Fourcroy's laboratory, where he not only acquired great dexterity in the ordinary duties of his situation, but became an expert and original analyst: he afterwards rose to high eminence in his profession, and his numerous and important contributions and discoveries are lasting monuments of his skill and industry.

Among the mineral analysts and improvers of analytical chemistry in this country, Mr. CHENEVIX deserves honourable mention. The following brief account of his contributions, and of the curious and mysterious controversy respecting Palladium, in which he was at one time involved, I copy from Dr. THOMSON'S *History of Chemistry*, vol. ii., p. 215.

"Mr. Chenevix deserves also to be mentioned as an improver of analytical chemistry. He was an Irish gentleman, who happened to be in Paris during the reign of terror, and was thrown into prison, and put into the same apartment with several French chemists, whose whole conversation turned upon chemical subjects. He caught the infection, and, after getting out of prison, began to study the subject with much energy and success, and soon distinguished himself as an analytical chemist. His analysis of corundum and sapphire, and his observations on the affinity between magnesia and silica, are valuable, and led to considerable improvements in the method of analysis. His analyses of the arseniates of copper, though he demonstrated that several different species exist, are not so much to be depended on; because his method of separating and estimating the quantity of arsenic acid is not good. This difficult branch of analysis was not fully understood till afterwards. Chenevix was for several years a most laborious and meritorious chemical experimenter. It is much to be regretted that he should have been induced, in consequence of the mistake into which he fell respecting palladium, to abandon chemistry altogether. Palladium was originally made known to the public by an anonymous handbill which was circulated in London, announcing that *palladium*, or new silver, was on sale at Mrs. Forster's, and describing its properties. Chenevix, in consequence of the unusual way in which the discovery was announced, naturally considered it as an imposition on the public. He went to Mrs. Forster's, and purchased the whole palladium in her possession, and set about examining it, prepossessed with the idea that it was an alloy of some two known metals. After a laborious

* Professor Frederick Stromeyer of Göttingen, who died in 1835, was a chemist of most distinguished analytical attainments, and deserves to be especially mentioned as one of the successful followers of the methods chalked out by Klaproth. He was Inspector-general of

the Apothecaries for the Kingdom of Hanover; and it was in discharging the duties of that office that he was led to notice certain peculiarities in the oxide of zinc, prepared for pharmaceutical uses: his further inquiries on this subject terminated in the discovery of cadmium.

set of experiments, he considered that he had ascertained it to be a compound of platinum and mercury, or an amalgam of platinum made in a peculiar way, which he describes. This paper was read at a meeting of the Royal Society by Dr. Wollaston, who was secretary, and afterwards published in their *Transactions*. Soon after this publication, another handbill was circulated, offering a considerable price for every grain of palladium made by Mr. Chenevix's process, or by any other process whatever. No person appearing to claim the money thus offered, Dr. Wollaston, about a year after, in a paper read to the Royal Society, acknowledged himself to have been the discoverer of palladium, and related the process by which he had obtained it from the solution of crude platina in aqua regia. There could be no doubt after this, that palladium was a peculiar metal, and that Chenevix, in his experiments, had fallen into some mistake, probably by inadvertently employing a solution of palladium, instead of a solution of his amalgam of platinum; and thus giving the properties of the one solution to the other. It is very much to be regretted that Dr. Wollaston allowed Mr. Chenevix's paper to be printed, without informing him, in the first place, of the true history of palladium; and I think that if he had been aware of the bad consequences that were to follow, and that it would ultimately occasion the loss of Mr. Chenevix to the science, he would have acted in a different manner. I have more than once conversed with Dr. Wollaston on the subject, and he assured me that he did everything that he could do, short of betraying his secret, to prevent Mr. Chenevix from publishing his paper; that he had called upon, and assured him, that he himself had attempted his process without being able to succeed, and that he was satisfied that he had fallen into some mistake. As Mr. Chenevix still persisted in his conviction of the accuracy of his own experiments after repeated warnings, perhaps it is not very surprising that Dr. Wollaston allowed him to publish his paper; though, had he been aware of the consequences to their full extent, I am persuaded that he would not have done so. It comes to be a question whether, had Dr. Wollaston informed him of the whole secret, Mr. Chenevix would have been convinced."

The Honourable EDWARD HOWARD also deserves a place among those eminent for their contributions to analytical chemistry. He was the first who accurately examined meteoric stones, and showed their identity from various places. (*Phil. Trans.*, 1802.)

§ XII.

BERGMAN was followed by two great and contemporary luminaries of chemical science, CAVENDISH* and SCHEELÉ, and though each attained distinction, they reached it by very different roads; showing the little influence of external circumstances upon the growth of inherent genius. The former was a leading person in the scientific circles of London; of noble family, and princely affluence. The latter, of humble origin and with limited means, made up for the deficiencies of place and fortune by zeal and economy, and, in the retirement of a Swedish village, raised a reputation that soon extended itself over Europe. In private life,

* Born in London, 1731; died at Clapham, 1810.

CAVENDISH was unambitious, unassuming, bashful, and reserved; he was peevishly impatient of the inconveniences of eminence; he detested flattery, and was uneasy under merited praise: he therefore shunned general society, and was only familiar in a very limited circle of friends. He was in the habit of dining every Thursday at the Royal Society Club, and there he always bore his faculties meekly; his conversation was varied and instructive; upon all subjects of science he was at once luminous and profound, and in discussion wonderfully acute.

Mr. CAVENDISH made two capital discoveries; one of which, that of the composition of nitric acid, has already been adverted to, and arose out of his researches on hydrogen, and on the products of its combustion, which terminated in ascertaining the composition of water. His first communication to the Royal Society relates to the analysis of the waters of Rathbone Place, and contains nothing worthy of particular notice. In 1776, he presented the same learned body with a dissertation on Inflammable, Fixed, and Nitrous Air, printed in the *Philosophical Transactions* for the same year, and full of important and original matter. Though his observations on fixed and on nitrous air were highly valuable, he had here been anticipated in some respects, and contemporary chemists were on most points his successful rivals; but his investigations relating to the properties of hydrogen were entirely his own; for, although it was known to others that that gas was generated by the action of certain acids on certain metals, though MAYOW had collected it, and HALES proved its combustibility, it may safely be asserted, that the phenomena of its production had entirely escaped attention, and that its principal properties were previously unknown. CAVENDISH shows that different metals afford different quantities of hydrogen; thus zinc yielded more than iron, and iron more than tin; and further, that the state of dilution and quantity of the acid, provided there was enough to dissolve the metal, did not affect either the quantity or properties of the air. In examining its properties, our author observed that it extinguished flame, destroyed animal life, and burned when pure with a pale blue flame: he determined its specific gravity, and found it was the lightest of all ponderable matter; hence its subsequent suggestion by Dr. BLACK and Mr. CAVALLLO as a substitute for rarefied air in the balloon: the former indeed failed in its application, and the latter only succeeded in the pretty experiment of elevating soap-bubbles by inflating them with hydrogen: he tried bladders, but the thinnest were too heavy, and tissue paper was permeable to the gas; it is singular he did not think of gold-beaters' skin, which, for similar purposes, had been recommended two centuries before by SCALIGER the grammarian*.

The first ascent in a balloon filled with hydrogen was made on the 1st of December, 1783, by Messrs. CHARLES and ROBERT, at Paris. In an hour and three-quarters, they alighted on the meadow of Nesle, twenty-five miles from the metropolis, and finding that the silk globe still retained great buoyant power, M. CHARLES ventured alone upon a second ascent. The sun had set, and the shades of evening were gradually condensing into the darkness of night; but his courage was rewarded by a most novel and sublime spectacle. He shot upwards with such celerity as to

* Supplement to *Encyclopædia Britannica*, Art. *Aëronautics*.

have attained the height of two miles in about ten minutes. The sun rose again to him in full orb, and from his lofty station he contemplated the fading luminary, and watched its parting beams till it once more sunk below the horizon. The vapours rising from the earth collected into clouds, and veiled it from his sight, while the pale rays of the moon scattered gleams of various hues over the fantastic and changing forms. The region in which the *aéronaut* now hovered was extremely cold; the balloon appeared fully distended, and upon opening the valve, the gas rushed out like a misty vapour into the external air. Prudence forbade this bold voyager to remain longer in such a situation; slowly therefore descending, he alighted in safety near the forest of Tour du Lay, having travelled about nine miles in thirty-five minutes. The barometer at the greatest elevation fell to 20.05 inches, and the thermometer sunk to 21° Fahrenheit; he therefore appears to have ascended to about 9,700 feet above the level of the sea.

The balloon has unfortunately proved but an abortive instrument in the hands of science. Messrs. BIOT and GAY-LUSSAC embarked from Paris on the 23rd of August, 1804, upon an *aërial* excursion devoted entirely to scientific inquiry. At the height of 13,000 feet, no peculiarity appeared to attach to electric or magnetic phenomena. On the 5th of the following September, GAY-LUSSAC undertook a second voyage alone, and attained the enormous height of 23,040 feet above the sea. Here he experienced excessive cold, his breathing was oppressed, and the pulse quickened; he, however, did not suffer the peril of his situation, or the peculiarities of his sensations, to distract his attention, and made several magnetic, electric, and hygrometric observations, without either novel or interesting results. Having alighted in safety in the neighbourhood of Rouen, he returned to Paris, and in the presence of M. THENARD analyzed the air brought from the upper regions, which proved analogous in composition to that at the surface of the earth.

To return to CAVENDISH: having determined the specific gravity, and other abstract properties of hydrogen gas, he proceeded to examine the results of its combustion, and found that, when mixed in certain proportions with atmospheric air, it exploded on the contact of flame, and deposited moisture in the vessel used for the experiment, a circumstance first noticed by MACQUER in 1766, and distinctly referred by WATT to the production of water in 1783. The experimental proofs, however, were still insufficient, and were supplied by CAVENDISH, in a paper given to the Royal Society in 1784. He found that a stream of pure hydrogen; burned either in air or oxygen, produced a vapour condensible into pure water. The same product resulted from the rapid combustion of a mixture of inflammable and dephlogisticated airs (hydrogen and oxygen gases). These experiments were subsequently verified by analytical researches: water was decomposed by LAVOISIER, by passing steam through a red-hot tube containing iron, which absorbs its oxygen, and pure hydrogen is liberated in the gaseous form. The decomposing energies of electricity have also been applied to this fluid, and it is found uniformly to be resolved into one volume of oxygen and two of hydrogen, which disappear on passing an electric spark through the mixture, and are converted into their weight of pure water.

The discovery of the composition of water, due to the joint labours of CAVENDISH and WATT, was a great step in chemical science, for it developed the hidden cause of many important phenomena of art and nature: no wonder, then, that the attention of the theorists was especially fixed upon it, some applying it to the explication of all difficulties; others rejecting even legitimate conclusions, and unwilling to strike this favourite element from the list of simple bodies.

CAVENDISH was an enemy to the new Nomenclature of chemistry, and was fond of foretelling its downfall; he disliked all innovations that were not rendered absolutely necessary by the progress of experiment, and would never adopt new opinions till fully and leisurely convinced of the fallacy of old ones.

While PRIESTLEY and CAVENDISH were contributing to the chemical eminence of Britain, SCHEELÉ* was diligently employed in the same pursuit under the patronage and guidance of BERGMAN, of whom it has been emphatically said, "that his greatest discovery was the discovery of SCHEELÉ," for he was the first to remark his promising genius and rising merit.

SCHEELÉ's publication, entitled *Chemical Observations and Experiments on Air and Fire*, is prefaced by an Introduction from the pen of his patron BERGMAN, setting forth the advantages of experimental science, and the benefits likely to result from the application of chemistry to the treatment and cure of diseases. Finding air necessary for the production of fire, SCHEELÉ first turned his attention to its analysis: he found that solution of liver of sulphur, and certain other sulphureous compounds, occasioned a diminution in the bulk of air to which they were exposed, equal to about one part in five; the flame of hydrogen, and that of sulphur, caused a similar decrease of bulk in air standing over water, and lime-water not being rendered in either case turbid by the residuum, no fixed air was formed. He then obtains empyreal air, (oxygen,) by the decomposition of nitric acid, and other processes; describes the method of transferring, collecting, and examining the gases; and endeavours to prove that heat is a compound of empyreal air and phlogiston; he also shows, by a direct experiment, that the absorption occasioned in atmospheric air by liver of sulphur is referable to the abstraction of its empyreal portion; that it totally absorbs empyreal air; and that upon adding to the residuary portion of atmospheric air, a quantity of empyreal air equal to that absorbed by the sulphureous liquor, an air is again compounded, similar in all respects to that of the atmosphere. The identity of these investigations

* Scheele is among the fortunate few, who, starting from an obscure original, have attained the zenith of scientific eminence. He was born in 1742, at Stralsund, where his father was a tradesman. His youthful days were passed in the house of an apothecary at Gottenburgh, where, by singular perseverance, and that kind of industry which is prompted by strong natural inclination, he acquired a valuable stock of chemical information. In 1773, having removed to Upsal, accident brought him acquainted with Berg-

man, who became his friend and patron, and to whose honour be it told, that, when Scheele's reputation afterwards rose to such a height as threatened to eclipse his own, instead of listening to the voice of jealousy, which, on such occasions, is too common a frailty, he became more zealous in behalf of his rival, and more indefatigable in the service of his friend. Scheele afterwards removed to Köping, in the neighbourhood of Stockholm, where he died in 1786.

with those of PRIESTLEY will not fail of being observed; but it must be recollected that they were entirely independent, and that although PRIESTLEY was in the field a little before him, SCHEELE was unacquainted with his proceedings.

The details concerning the nature of air, are followed by an inquiry into the properties of Heat and Light, which, though somewhat tainted by false theory, bears the stamp of an able and original mind. Adverting to the reflection of the rays from a common fire, by a concave metallic mirror, he remarks, that they passed in straight lines, without suffering any derangement from currents or undulations in the atmosphere which they traverse; that glass intercepts the heat, but not the light; that a mirror of glass reflects the light, but absorbs the heat, whereas metal reflects both: the metal, therefore, if clean, does not become heated; but, if blackened over a smoking candle, it then absorbs heat, and becomes very warm. He notices the distinction between heated air and heat emanating in straight lines: "represent to yourself a little hillock of burning coals; in this case, the heat darting from this hillock all around is that which may be reflected by a metallic polished plate; that, on the contrary, which rises upwards, and may be driven by winds to and fro, unites with air. I call the first kind, by way of distinction, *radiant heat*." Discussing the phenomena of solar and terrestrial radiation, he considers their apparent differences to result, not from any absolute difference in the nature of the emanating particles, but in their quantity. "There is no doubt," he says, "about the light of the sun and that of a burning candle being the same thing; for this affects the eye in the same manner as the sun, and represents the same colours through the prism, but being weaker, it is no wonder that its beams, collected in a burning-glass, will not burn: nor is there any doubt about light being a body in the same manner as heat, but I cannot persuade myself that light and heat are the same thing, since experiment proves the contrary." Finding that light blackened nitrate of silver, though heat alone had no effect upon it, he considers light as containing an inflammable principle, and shows that *luna cornea*, after long exposure to the sun's rays, is no longer perfectly soluble in ammonia, but leaves a portion of reduced silver; he also shows, that when put into water, it forms muriatic acid in the light, but not in the dark; and that the violet rays produce these effects more rapidly and powerfully than the other coloured rays, and even than white light.

Among these experiments on air and fire some curious facts are detailed, respecting the spontaneously inflammable compound discovered early in the last century by HOMBERG, and called *Pyrophorus*; it is shown that potash is necessary to its formation, and that alum crystallized by ammonia is unfit for its production. The evolution of hydrogen, during the action of iron upon sulphur, and of nitrogen in the detonation of fulminating gold, are also among the facts contained in this essay; as well as a variety of curious circumstances relating to the effect of vegetation and respiration upon air; and it closes with an account of the properties of Sulphureted Hydrogen.

Exclusive of the experimental details, there is little to praise in the *Treatise on Air and Fire*, for the theories which it contains are often

strained and illicit, and do not easily admit of being rendered intelligible by the translation of the phlogistic language into that of the modern school: nor are SCHEELE's detached essays altogether free from similar blemishes; but then they are so rich in facts, that we the more easily overlook theoretical failings. His dissertation on Manganese, for instance, with a description of the principal salts of that metal, contains the important discovery of Dephlogisticated Muriatic Acid, or, as it is now termed, Chlorine; and his views respecting it, and the nature of the muriatic acid, are remarkably correct, and perfectly intelligible in present theory, if we substitute hydrogen for phlogiston; it will then be found that muriatic acid is regenerated by the addition of hydrogen to chlorine, and that hydrogen is evolved by the abstraction of chlorine from muriatic acid.

BERTHOLLET's hypothesis of the nature of chlorine for a time superseded the theory of SCHEELE, and under the name of Oxymuriatic Acid, it was regarded as a compound of oxygen and muriatic acid; but, in 1811, Sir H. Davy, in an important dissertation on the subject, published in the *Philosophical Transactions*, demonstrated the errors of the French school, revived the doctrine of SCHEELE, and established it by a body of evidence now generally received. Berthollet, however, has the distinguished merit of first suggesting the application of chlorine to bleaching upon the large scale.

In his essays on Fluor Spar, and its acid, SCHEELE has committed several errors, among which the most glaring is the conclusion which he draws respecting the formation of siliceous earth. When powdered fluor spar is distilled with sulphuric acid in a glass retort, the silica of the glass is dissolved by the acid of the fluor, carried over with it in the gaseous state, and in part deposited in the receiver containing water; SCHEELE inferred that siliceous earth was here formed by the union of fluoric acid and water; and, persisting in his error, he endeavours to show that the same formation ensues in metallic vessels, and therefore independent of glass; but he takes no due precautions against the presence of silica in the fluor spar which he used. Yet there is much to praise in the methods of analysis employed in investigating the nature of this singular body; it is a subject full of difficulties, and can scarcely be called complete even at the present day, though it has engaged the attention of the most acute analysts. The acids of arsenic and of molybdenum were first examined by SCHEELE, and he first showed the difference between Molybdenum and Plumbago, and pointed out the existence of carbon and iron in the latter.

In 1778, SCHEELE made known the preparation of Arsenite of Copper, and recommended it as an useful and permanent colour in oil and water painting; and, in 1779, he took up the important subject of the decomposition of neutral salts by unslaked lime and iron. He found upon the iron hoops of a tub of salted turnips, which had been placed in a damp cellar, a quantity of salt resembling mineral alkali, and was struck with the circumstance, "knowing that the attraction of acid of salt is weaker for iron than for mineral alkali." He dipped plates of several other metals into solutions of common and Glauber's salt, but found that iron only was effectual in their decomposition, and that the action was more rapid in a damp cellar than elsewhere; he also found that quicklime

decomposed those salts in the same situation; and that the decomposition was partly dependent upon the presence of carbonic acid in the atmosphere of the vault.

In the essays on Milk and Sugar-of-milk, there are many curious circumstances respecting the action of re-agents upon that liquid, and these papers deserve particular notice, as among the earliest specimens of the analysis of animal fluids. SCHEELE observes that, from his experiments, it appears "that the acid of milk is an acid of a peculiar kind, and though it expels the vinegar from acetated vegetable alkali, yet it seems destined, if I may so speak, to be vinegar." He attributes its difference to the want of some ferment, and shows that the addition of a little brandy to milk, causes it, when fermented, to afford good vinegar. The method of obtaining the Citric and some other vegetable acids, by decomposing their compounds with lime by sulphuric acid, is also among SCHEELE's discoveries; and his essays on Tungsten, on the preparation of Calomel in the humid way, on Urinary Calculi, on Ether, and on Benzoic acid, each contain important facts, and display new modes of inquiry: they deserve the perusal of those who may be engaged in investigations relating to the several subjects of which they treat.

The last essay to which I shall advert in this sketch of SCHEELE's discoveries, was published in 1782, and is entitled *Experiments on the Colouring Matter of Prussian Blue*. This very singular substance was accidentally discovered early in the last century, by DIESBACH, a colour-maker at Berlin: the preparation was, however, kept secret till published by WOODWARD, in 1724. In 1752, MACQUER's dissertation upon it presented a connected view of its chemical history, which, however, was imperfect and unsatisfactory. SCHEELE directed his attention to the discovery of the principle upon which its colour depended. He shows, that the salt produced, by digesting Prussian blue in caustic potash, is a triple compound of the colouring principle, iron and potash; iron being, as he supposes, the medium by which the colouring matter is attached to the alkali: this salt he decomposed by distilling its aqueous solution with a small quantity of concentrated vitriolic acid, and the liquor which passed into the receiver carried with it a great portion of the colouring principle, which has since been termed *Prussic Acid*. SCHEELE then goes on to show that the action of this acid, in its pure state, upon metallic solutions, is very different from that which it exhibits when combined with alkalis. United with lime, he found that it afforded precipitates in the greater number of metallic solutions. Our author enters into much interesting speculation and experiment, relating to the nature of this colouring principle; and considering the difficulty of the subject, treats it with perspicuity and success. This dissertation on Prussian blue was nearly his last contribution to the science which he had so much embellished and improved, for he died in 1786, at the age of forty-four.

It requires no deep inquiry, or minute investigation, to detect, in the researches of PRIESTLEY, SCHEELE, and CAVENDISH, the materials of which their contemporary, LAVOISIER, aided by several celebrated chemists of the French school, constructed his new theory; and a retrospect of the works of MAYOW and HOOKE will show that the Antiphlogistic System almost necessarily arose out of a combination of their views with the more

modern discoveries. In maintaining, however, that the materials employed in raising this celebrated system were of foreign, and chiefly of British origin, we must not be understood as detracting from the indisputable merit of those to whose persevering diligence chemistry owes so much of its present importance; by whom the scattered and unconnected facts of the science were brought together and arranged; and who cleared its paths of the numerous obstructions with which they were previously beset.

§ XIII.

THE numerous and important contributions with which the eminent but unfortunate LAVOISIER* enriched the chemistry of his time are to be found in the *Memoirs of the Royal Academy of Sciences of Paris*; but as he has chiefly been celebrated as a theorist, I shall here confine myself to such of his inquiries as bear upon that memorable reform in the science, by which a new nomenclature was introduced, and which ended in the banishment of phlogiston. In this reform LAVOISIER took the lead, and though his original investigations connected with it are few and comparatively unimportant, he availed himself with so much skill and success of the labours of others, as, by placing them in new points of view, and exhibiting their unexpected applications, to render them almost his own. LAVOISIER's character has, in some measure, suffered by the misguided zeal of his admiring commentators, who, not satisfied with allowing him due merit for the logical precision and sagacity of induction which he brought into chemistry, have represented him as having the experimental activity of PRIESTLEY, and the laborious diligence of SCHEELE. But LAVOISIER, though a great architect in the science, laboured little in the quarry; his materials were chiefly shaped to his hand, and his skill was displayed in their arrangement and combination.

A connected view of his principal reasonings and most prominent researches will be found in his *Elemens de Chimie*, published at Paris, in 1789. This work, in every way important, is divided into three principal sections: the first treats of the formation and decomposition of aëriiform fluids, of the combustion of simple bodies, and the formation of acids: the second, of the combination of acids with salifiable bases, and of the formation of neutral salts: and the third, of the instruments and operations of chemistry.

The first section opens with a discussion concerning the Nature and Operations of Heat, which he defines as a real and material substance, or a very subtile fluid, separating the particles of bodies from each other, by insinuating itself among them. This exquisitely attenuated substance he calls *Caloric*, and though he allows that light, in many instances, produces phenomena analogous to those of heat, though they have certain qualities in common, their identity not having been demonstrated, they are to be considered as distinct; he then dwells upon the requisite caution in investigating the properties of caloric, since they are known

* Born in 1743 at Paris, where he fell a victim to the Revolution, on the 8th of May, 1794.

only by fleeting and difficultly ascertainable effects: "It is in those things," he says, "which we neither see nor feel, that it is especially necessary to guard against the extravagances of the imagination, which always inclining to overstep the bounds of truth, is difficultly restrained by the narrow limits of facts." The influence of heat upon the states of bodies is then illustrated, and their relative capacities for heat alluded to. He says that solidity, liquidity, and aëriform elasticity, are only three different states of existence of the same matter, or three particular modifications which almost all substances are susceptible of assuming successively, and which solely depend upon the degree of temperature to which they are exposed, or, in other words, "upon the quantity of caloric with which they are penetrated." In consequence of this influence of caloric, the possible existence of certain metallic substances in our atmosphere is inferred; "such a substance, for instance, a little more volatile than mercury, might exist there." LAVOISIER then proceeds to the analysis of atmospheric air, which he effects by exposing fifty cubical inches of it to heated mercury; it undergoes a decrease equal to one-sixth of its original bulk, and becomes unfit for respiration and combustion; at the same time, the quicksilver is partly converted into a reddish matter, 45 grains of which heated red-hot in a proper retort, afforded 41.5 of running mercury, and 7 or 8 cubical inches of gas, eminently supporting combustion, and being the dephlogisticated air discovered by PRIESTLEY. The mixture of the 42 cubical inches of the mephitic air of the retort, with the 8 cubical inches of dephlogisticated air, separated from the mercury, re-produce 50 cubic inches of atmospheric air.

LAVOISIER considered all aëriform fluids as compounds of a ponderable basis, with caloric and light: in the above experiment, the ponderable part of the dephlogisticated air unites to the quicksilver, but the union is effected so slowly, that the phenomena of combustion are not perceived; if, however, red-hot iron wire be introduced into the air evolved from the red compound of quicksilver, it acts readily upon it, and its decomposition is attended by the copious evolution of heat and light, while the iron undergoes an increase in weight equivalent to that of the air absorbed.

In discussing the principles of nomenclature, most applicable to the different aëriform fluids, LAVOISIER retains, after the example of MACQUER, the word *gas*, used first by VAN HELMONT, as a generic term for all that differ from atmospheric air: he shows that one of the most general properties of vital or dephlogisticated air, is, to form *acids*, and hence he gives it the name of *oxygen gas*; the other element of the atmosphere is called *azotic gas*, from its fatal effects upon animal life, a term, "commendable," says LAVOISIER, "because it only expresses a matter of fact."

The combustion of sulphur, phosphorus, and carbon, is next shown to be attended with the same phenomena as that of iron, namely, the extrication of heat and light, and the union of the ponderable part of the oxygen with the combustible; and the principles of nomenclature applicable to these different compounds are developed. Where oxygen does *not* form an acid, its compounds are termed *oxides*; and where more than one oxide, or acid, is formed, the termination of the base

indicates its nature: thus there are four compounds of nitrogen with oxygen, two oxides, and two acids; the former are respectively termed *nitrous* and *nitric oxides*; and the latter, *nitrous* and *nitric acids*; the *minimum* and *maximum* of oxygen being in each case designated by the termination *ous* and *ic*. The term *hydrogen* is applied to inflammable air, shown by CAVENDISH to be the basis of *water*; and fixed air is called *carbonic acid*, since it is identical with the result of the combustion of charcoal, or carbon, in oxygen. In connexion with the latter subject, LAVOISIER made the important discovery of the production of carbonic acid by the combustion of the diamond. The destruction of this gem by fire was demonstrated by the Florentine Academicians as early as 1690; they exposed a diamond to the focus of a burning lens, and found that it was entirely evaporated; and Francis the First, of Germany, witnessed the same phenomenon in the heat of a furnace. LAVOISIER proved that the diamond underwent no change when air was excluded; and that, when ignited in oxygen gas, it produced carbonic acid: whence the inevitable conclusion that the diamond and charcoal are identical in their nature; and that the vast difference in their appearance and mechanical qualities is the result of aggregation; that the one is crystallized; the other in a less indurated form. Unprecedented as such an idea may seem, it is not only warranted by the experiments of LAVOISIER and others, but also in some degree supported by analogy. Thus, when argillaceous earth, which is a white pulverulent substance, is aggregated by mechanical attraction into a crystalline form, it constitutes the sapphire, one of the hardest and least destructible of the gems. In one state, the earth is soft, and readily soluble in acids; in the other, its insolubility equals its induration: but there is one anomaly, relating to the conducting power of the diamond and charcoal in regard to electricity; the former ranks among the non-conductors, the latter is a good conductor; and hitherto mechanical texture has not been clearly shown, in any strictly analogous cases, to interfere with the power of conducting electricity.

Among those who have further explored the phenomena of the combustion of the diamond, and who have verified and extended the original views of LAVOISIER, we find the names of some of the most eminent European Philosophers. Few subjects in Chemistry have been so carefully pursued, and the united results of different experimentalists have rarely tallied with the precision which these researches present*.

* That the quantity of carbonic acid, afforded by a given weight of diamond, is the same as that yielded by a similar quantity of charcoal, is the great proof of the identity of those apparently dissimilar substances; this was demonstrated in the year 1796, by the refined and elegant experiments of the late Mr. Tennant.

Mr. Smithson Tennant was a profound philosopher, and a matchless companion: "his learning was without pedantry; his wit without sarcasm;—he was deep, but always clear; gentle, but never dull." To those who knew him not, it is scarcely possible to offer an adequate representation of his singularly pleasing and

enlightened character; by those who enjoyed his acquaintance, and partook of his social hours, his extent of knowledge, his happy and unrivalled talent for conversation, his harmless but brilliant flashes of merriment, and all his amiable peculiarities, can never be forgotten. Mr. Tennant was born in Yorkshire in 1761, and died at Boulogne in 1815. He was the discoverer of the metals Iridium and Osmium, and the author of several important contributions to chemical science.

See Biographical Account of Smithson Tennant, Esq., in THOMSON'S *Annals of Philosophy*, vol. vi.

LAVOISIER was the first who examined with requisite accuracy the products of the distillation of vegetable and animal substances, and who drew a proper line of distinction between the *educts* and *products* thus afforded; he also inquired, with more success than any of his predecessors, into the phenomena of *fermentation*, and by examining the contents of certain vegetable juices previous to and after that process, he drew some very curious conclusions respecting the changes that take place.

In his observations upon *salifiable bases*, and the formation of *neutral salts*, LAVOISIER has described the phenomena of the solution of metals in the various acids: he adverts to the oxidizement of the metals previous to their solution, and to the consequent liberation of hydrogen; and has the following acute surmise respecting the nature of the alkaline earths, which then were considered as elementary bodies:—"From these phenomena it appears that oxygen is the bond of union between metals and acids, and from this we are led to suppose that oxygen is contained in all substances which have a strong affinity with acids; hence it is very probable that the four eminently salifiable earths contain oxygen, and that their capability of uniting with acids is produced by the intermediation of that element. What I have formerly noticed relative to these earths, namely, that they may very possibly be metallic oxides, with which oxygen has a stronger affinity than with carbon, and consequently are not reducible by any known means, is considerably strengthened by the above considerations." Sir H. DAVY, in showing the combustibility of the metals of the alkalis in carbonic acid, has verified this anticipation.

In the second part of the *Elements*, LAVOISIER treats of the formation of Neutral Salts, and throws out new and important views relating to the constitution of chemical compounds. Speaking of the influence of Light as a chemical agent, he adverts to its singular action upon the vegetable kingdom, and supposes that it combines with certain parts of vegetables, and that the green of their leaves, and the various colours of their flowers, are chiefly owing to this combination. "This much," he says, "is certain, that plants which grow in darkness are perfectly white, languid, and unhealthy, and that to make them acquire vigour, and recover their natural colours, the direct influence of light is absolutely necessary. Somewhat similar takes place even in animals. Mankind degenerate to a certain degree when employed in sedentary manufactures, or living in crowded houses, or in the narrow lanes of large cities; whereas they improve in their nature and constitution in most of the country labours which are carried on in the open air."

LAVOISIER incorrectly refers the influence of light to its direct combination; but it rather appears to modify, or exalt, the mutual agencies of bodies: of this we have some remarkable instances; as in the action of chlorine upon hydrogen, and upon carbonic oxide; and of chlorine, and several of the chlorides, upon water; from which it occasions the evolution of oxygen, and the production of muriatic acid; this change gave rise to the idea of the existence of oxygen and muriatic acid as the components of chlorine; the agency of water and the nature of muriatic acid not having been taken into the account.

In his observations on the combinations of oxygen, the conditions requisite to the oxidizement of bodies are mentioned; such as the dimi-

nution of aggregation by heat, which causes many substances to attract the oxygen of the atmosphere; their ignition with nitre, or with chlorate of potassa; and their solution in certain acids, especially the nitric. The combinations of the different combustible substances are next reviewed, and those of the acids and of some other compound bodies.

The third part of the *Elements* is occupied with the description of a variety of chemical operations, which were exceedingly improved and extended by LAVOISIER. He shines as the inventor of costly and complicated apparatus, the greater part of which might, however, have been superseded by simpler and cheaper utensils.

This sketch of the contents of LAVOISIER's *Elements of Chemistry* will sufficiently show the extent and perspicuity of his views as a theorist; and though the arrangement is open to objection, it was calculated for the use of the student, and fitted to display the strongest parts of the anti-phlogistic system in the most favourable light: it was, indeed, impossible that any one of unbiassed judgment could seriously retain the phlogistic doctrines after the perusal of this masterly refutation. If we look for the abstract facts upon which this refutation rests, we shall search in vain, either in the works of LAVOISIER, or in those of his contemporaries: they were furnished from other quarters, and will, I think, chiefly be found in the writings of MAYOW and HOOKE, and in those of PRIESTLEY and SCHEELÉ. The prominent features of the French theory are its explanation of the phenomena of combustion and of acidification, the presence of oxygen being deemed essential in both cases. That air is the food of fire was known in the remotest ages; that it causes the increase of weight sustained by metals during their fusion and calcination, was shown by REY early in the seventeenth century; that a part only of the atmosphere, is concerned in the support of flame, was explained by HOOKE in 1667; and that the vital or igneous spirit, as he terms it, of the atmosphere, is concerned in the formation of acids, was asserted by MAYOW in 1674. Here, without advancing into the eighteenth century, we have, in explicit detail, all the facts and arguments requisite for the construction of the French theory; but if to these we add the discovery of Oxygen by PRIESTLEY, and of the composition of water by CAVENDISH and WATT, what then becomes of its claim to originality?

It must be regretted that those who have censured LAVOISIER with occasional uncandid and unacknowledged appropriation of the thoughts of others, have some grounds for the accusation. In bringing forward his theory of combustion, why did he not refer to the opinions of REY and MAYOW? why refuse praise and acknowledgment to BLACK, and SCHEELÉ, and CAVENDISH; or why appropriate the discovery of oxygen, in the face of the prior, indisputable, and known claims, of his friend and contemporary, PRIESTLEY? These are questions we cannot now answer; but those who have grounded indiscriminate and severe censure upon such accusations, have neither been animated by the unprejudiced spirit of true philosophy, nor guided by the unbiassed love of truth. It must be remembered that LAVOISIER was never fairly confronted by these rivals and antagonists; that unintentional inadvertency often accompanies scientific ardour; that, in the eagerness of pursuit, he may have neglected that which, in a calmer hour, he would have seen, regretted, and acknowledged;

and that, in the hurry of discussion and heat of controversy, he was suddenly summoned to eternity*.

* Two scarce volumes of the posthumous works of Lavoisier are extant, consisting, in great measure, of extracts from, and sketches of, his different papers read before the Royal Academy of Sciences; but several original Observations and Essays are also dispersed among them. They, in some degree, justify the observations which I have made in the text, that, had Lavoisier lived, he would have done merited justice to his predecessors and contemporaries, for he candidly reviews their opinions, and compares them with his own; at the same time, the following passage cannot be regarded as perfectly candid towards Rey, who, as I have shown above, founded his arguments, not upon hypothesis, but upon experiment.

I insert a long quotation, that there may be no misunderstanding upon the subject.

After stating the prevailing phlogistic notions entertained at that period, he proceeds as follows:—"Tel étoit l'état des connoissances, lorsqu'une suite d'expériences, entreprises en 1772 sur les différentes espèces d'air, ou de gaz qui se dégagent dans les effervescences et dans un grand nombre d'opérations chimiques, me firent connoître, d'une manière démonstrative, quelle étoit la cause de l'augmentation de poids, qu'acquîèrent les métaux lorsqu'on les expose à l'action du feu. J'ignoreis alors ce que Jean Rey avoit écrit à ce sujet en 1630; et quand je l'aurois connu, je n'aurois pu regarder son opinion à cet égard, que comme une assertion vague, propre à faire honneur au génie de l'auteur, mais qui ne dispensait pas les chimistes de constater la vérité de son opinion par des expériences. J'étois jeune, j'étois nouvellement entré dans la carrière des sciences, j'étois avide de gloire, et je crus devoir prendre quelques précautions pour m'assurer la propriété de ma découverte. Il y avoit à cette époque, une correspondance habituelle entre les savans de France et ceux d'Angleterre; il regnoit entre les deux nations, une sorte de rivalité qui donnoit de l'importance aux expériences nouvelles, et que portoit quelquefois les écrivains de l'une ou de l'autre nation, à les contester à leur véritable auteur; je crus donc devoir déposer, le 1^{er} Novembre, 1772, l'écrit suivant cacheté,

entre les mains du Secrétaire de l'Académie. "Ce dépôt a été ouvert à la séance du 5^{me} Mai suivant, et mention du tout a été faite en tête de l'écrit. Il étoit conçu en ces termes:—

"Il y a environ huit jours que j'ai découvert, que le soufre en brûlant, loin de perdre de son poids, en acquîeroit au contraire; c'est à dire, que d'une livre de soufre on pouvoit retirer beaucoup plus d'une livre d'acide vitriolique, abstraction faite de l'humidité de l'air; il en est du même du phosphore: cette augmentation de poids vient d'une quantité prodigieuse d'air qui se fixe pendant la combustion, et qui se combine avec les vapeurs.

"Cette découverte que j'ai constatée par des expériences que je regarde comme décisives, m'a fait penser que ce qui s'observoit dans la combustion du soufre et du phosphore, pouvoit bien avoir lieu à l'égard de tous les corps qui acquîèrent du poids par la combustion et la calcination: et je me suis persuadé, que l'augmentation de poids des *chaux* métalliques, tenoit à la même cause. L'expérience a complètement confirmé mes conjectures: j'ai fait la réduction de la litharge dans des vaisseaux fermés, avec l'appareil de Hales, et j'ai observé, qu'il se dégageoit, au moment du passage de la *chaux* en métal, une quantité considérable d'air, et que cet air formoit un volume au moins mille fois plus grand que la quantité de litharge employée. Cette découverte me paroissant une des plus intéressantes qui aient été faite depuis Stahl, j'ai cru devoir m'en assurer la propriété, en faisant le présent dépôt entre les mains du Secrétaire de l'Académie, pour demeurer secret jusqu'au moment où je publierai mes expériences."

(Signé)

"LAVOISIER."

"En rapprochant cette première notice de celle que j'avois déposée à l'Académie le 20^{me} Octobre précédent, sur la combustion du phosphore, du mémoire que j'ai lu à l'Académie à sa séance publique de Pâques 1773, enfin, de ceux que j'ai successivement publiés, il est aisé de voir, que j'avois conçu dès 1772, tout l'ensemble du système que j'ai publié depuis sur la combustion. Cette théorie à laquelle j'ai donné de nombreux développemens en 1777, et que j'ai porté,

Although LAVOISIER made few original discoveries, his talents were perhaps more usefully employed in setting forth and elucidating the researches of others, a task which he performed with great skill and success: in reviewing hypotheses, he diligently contrasts them with facts; weight and measure, which had been introduced into chemistry by BERGMAN, were strictly insisted upon in all his manipulations, and in his hands chemistry assumed the features of a new branch of knowledge, and put on its present character.

Connected with the labours of LAVOISIER is the celebrated reform of *chemical nomenclature* effected by him and his associates, among the most eminent of whom we may enumerate GUYTON MORVEAU*, FOURCROY†, and CHAPTAL‡. The former, amidst varied occupations, pursued

presque dès cette époque à l'état où elle est aujourd'hui, n'a commencé à être enseignée par Fourcroy, que dans l'hiver de 1786 à 1787; elle n'a été adoptée par Guyton Morveau, qu'à une époque postérieure: enfin, en 1785 Berthollet écrivait encore dans le système du phlogistique. Cette théorie n'est donc pas, comme je l'entends dire, la théorie des Chimistes François: elle est la mienne, et c'est une propriété que je réclame auprès de mes contemporains et de la postérité."

* Born at Dijon, 1737; died, 1815. "Guyton Morveau," says Davy, "was very old when I made his acquaintance; between seventy and eighty, and very feeble. Though he had been a violent republican, he was Bonaparte's director of the mint, and a baron of the empire. His manners were mild and conciliatory; and it is a proof of the energy of his mind, that having promised his vote to a person, as Corresponding Member of the Institute, he kept his promise, and my election wanted only his voice to be unanimous. Having never, when in France, inquired into the intrigues connected with elections, or interested myself about them, I should not have known this had he not himself told me so when I dined afterwards at his house."

—*Davy's Life*, by Dr. JOHN DAVY.

† Born at Paris, 1755; died, 1809.

‡ I have extracted the following notice of Chaptal from the address of H. R. H. the Duke of Sussex, delivered at the Anniversary Meeting of the Royal Society, November 30, 1832:—

"Jean Antoine Chaptal, Comte de Chanteloup, was born in 1756, and died in April last, in the 76th year of his age. He was Professor of Chemistry at Montpellier before the Revolution, and was one of the most active cultivators of chemical science before that event, in conjunction

with Monge, Fourcroy, Berthollet, Guyton de Morveau, and the illustrious Lavoisier. In the year 1793, upon the threatened invasion of France by the Allies, when saltpetre was not to be procured in sufficient quantities for the manufacture of the powder wanted by the French armies, he was invited by the Committee of Public Safety to superintend the establishments for that purpose; and his chemical knowledge so greatly improved the method followed in its manufacture, as in a very short time to make the produce greatly exceed the demand. He was made *Ministre de l'Intérieur* by Napoleon, and continued under the Empire to fill many important situations. He was the author of considerable works on chemistry, on the application of chemistry to the arts, on the application of chemistry to agriculture, on the art of making wines, and on the art of dyeing cotton and wool, which are written in a very perspicuous and elegant style, and which have enjoyed a very considerable popularity in France. The labours of his whole life, in fact, were devoted to the improvement of those manufactures whose perfection depended more or less upon the most correct and economical application of chemical principles; and, after his distinguished countryman, Berthollet, he must be placed in the first rank of those who have benefited the arts through the medium of chemical science."

"Chaptal," says Sir H. Davy, "for a long while Bonaparte's Minister of the Interior, was an active, amusing, intriguing courtier and chemist, and somewhat acquainted with the state of the chemical arts in France. Not very exact in conversation, and a little boasting, yet good natured, and with lively man-

chemistry with successful diligence, and, had he given nothing else to the science, his name deserves to be transmitted to posterity, as the inventor of the means of destroying infection by acid vapours, the efficacy of which he first pointed out in the year 1773. His first essay on the reform of nomenclature was published in the *Journal de Physique* for May, 1782, and although it was strenuously opposed by the colossal power of the Royal Academy of Paris, the plan was not only afterwards approved, but prosecuted by the eminent chemists of that metropolis. The different papers and correspondence relating to this subject are, in many respects, curious and interesting, from the difference of opinion which prevailed respecting the terms he adopted, and the ultimate benefit likely to result from the reformation. FOURCROY is a well-known name in the chemical world; his works rank among the most celebrated which France has produced in the science: he is the first author who published a *System* of chemistry. CHAPTAL was a successful contributor to the Chemistry of the Arts.

The difficulties attending an entire reform in the nomenclature of chemical science may be well imagined; they were encountered with considerable address; and it must be confessed, that, while it particularly tended to the dissemination of the anti-phlogistic doctrines, it facilitated the general acquisition of the science; the ludicrous terms of the alchemists were rejected, and names founded upon the nature of compound bodies, and upon the leading qualities of elementary substances, became their more sensible substitutes. It is true, that the progress of science has rendered much of the French nomenclature objectionable, and that it has been requisite to modify many of its terms, more especially such as were founded on erroneous theory: others, though objectionable, have been retained, rather than submit to the serious inconvenience to which repeated innovations tend; and nothing short of absolute necessity can justify us in changing old and accepted terms for those of more recent coinage. In the selection of names necessarily new, some leading and obvious property, independent of theory, should be selected as their basis; such terms as *iodine*, *bromine*, and *chlorine*, are in this respect unexceptionable. To the subjoined opinion upon this subject, by Sir H. DAVY*, I entirely subscribe:—

“Simplicity and precision ought to be the characteristics of a scientific nomenclature; words should signify things, or the analogies of things, and not opinions. If all the elements were certainly known, the principle adopted by LAVOISIER would have possessed an admirable application; but a substance in one age supposed to be simple, in another is proved to be compound; and *vice versâ*. A theoretical nomenclature is liable to continued alteration; *oxygenated muriatic acid* is as improper a name as *dephlogisticated marine acid*. Every school believes itself in the right; and if every school assumes to itself the liberty of altering the names of chemical substances, in consequence of new ideas of their composition or

ners, and quiet and ready conversation. More a man of the world than any of the savants of his day in France. It is said that he was author of Napoleon's decrees aimed at the commerce of England; if

so, he has contributed more than any other individual, except his master, to the military glory of the modern Briton.”

* *Elements of Chemical Philosophy*, pp. 46, 47.

decomposition, there can be no permanency in the language of the science; it must always be confused and uncertain. Bodies, which are similar to each other, should always be classed together; and there is a presumption that their composition is analogous. Metals, earths, alkalies, are appropriate names for the bodies they represent, and independent of all speculative views; whereas, oxides, sulphurets, and muriates, are terms founded upon opinions of the composition of bodies, some of which have been already found erroneous. The least dangerous mode of giving a systematic form to a language seems to be to signify the analogies of substances by some common sign affixed to the beginning, or the termination of the word. Thus, as the metals have been distinguished by a termination in *um*, as *aurum*, so their calciform, or oxidated state, might have been denoted by a termination in *a*, as *aura*; and no progress, however great, in the science, could render it necessary that such a mode of appellation should be changed. Moreover, the principle of a composite nomenclature must always be very limited. It is scarcely possible to represent bodies consisting of five or six elements in this way, and yet it is in such difficult cases that a name implying a chemical truth would be most useful."

Among the causes that have contributed to the recent progress of chemical science, we have already had occasion to advert to the *doctrine of definite proportionals*, which has enabled us to submit many of the phenomena of chemistry to calculation, and which promises to elucidate some of its most abstruse parts upon mathematical principles; but the chief source of the rapid advancement of chemistry during the present age, is doubtless the discovery of *the relation of electrical to chemical changes*; a discovery which has unfolded entirely new views of the mutual agencies of bodies, and which has equally furnished the theoretical and practical chemist with materials for speculative and experimental inquiry.

The curious experiments of GALVANI upon the convulsions excited in the limbs of animals, by the application of certain metals to their muscular and nervous fibres, led VOLTA to investigate the cause of such phenomena, and to attempt the accumulation of the electricity, to which he suspected they were to be referred: this he attained by successive alternations of different metals with substances acting chemically upon one of them; and he found that the extremities of such a pile were in opposite electrical states, and that the intensity of the electricity augmented the number of alternations. This instrument has been productive of vast discoveries, which are yet far from exhausted, and has given rise, in the hands of DAVY, to a new and curious department of chemical philosophy, into the history of which I shall enter a little more in detail, chiefly with a view of showing the singular talent and sagacity with which a difficult and intricate branch of science was successfully pursued and illustrated by that eminent individual.

It appears, from the "*additional observations*," appended to his *Chemical Researches, upon Nitrous Oxide, &c.*, published in 1800, that Sir H. DAVY had no sooner heard of VOLTA's researches, than his mind was awakened to their bearings upon chemical changes; and from that period, to the time of his first publication upon the subject, he seems not to have lost sight of the inquiry; indeed it was his characteristic habit

to examine without delay all novel results of other philosophers, and when he had confirmed their accuracy, he generally rendered them subservient to further discovery. Accordingly, we find that the first paper which he presented to the Royal Society (read the 18th of June, 1801,) was "*An Account of some Galvanic Combinations formed by the Arrangement of single metallic Plates and Fluids, analogous to the Galvanic Apparatus of Volta,*" and it contains several curious and interesting facts upon a subject which now began to excite general attention, and attracted the notice of many skilful experimentalists. The first harvest of fame, however, in this field of inquiry, was reserved for DAVY; and the *Bakerian Lecture* for 1806 contains a series of propositions and experiments, in reference to the chemical agencies of electricity, which at once display the masterly energies of the author's mind in passing from experiment to theory, and in the employment of that theory as the source of new, profound, and elaborate researches. About the time this paper was published, a great and important question respecting the agencies of electricity was undecided; it was not known whether electricity had the power of *generating* certain forms of matter, or whether they were merely *elicited*, by its influence, from compounds which escaped common modes of detection. Water, for instance, was found not merely to be resolved into its ultimate gaseous components, but their evolution was constantly connected with the appearance of acid and alkaline matter, and *that*, although every precaution was apparently taken to exclude foreign matters and all sources of impurity. Hence it was imagined that water either contained the elements of these bodies, or that it produced them by uniting with the electric fluids, or that they were actually conveyed, by some mysterious route, from the cells of the pile; indeed, it would be useless to enumerate all the speculations originating in these paradoxical phenomena; but it will be profitable to glance at the manner in which the difficulties were encountered by our author. He first repeated all that had been done by others, and criticized and compared their proceedings; he then electrized distilled water, and found, as they had found, the evolution of saline, alkaline, and acid bodies; but he also found that the more rigidly he purified the water, the smaller was the evolution of these products; a fact militating against their supposed source; still, however, they made their appearance. He now directed his attention to the vessels which were used, and succeeded in referring to *them* several extraneous bodies; thus glass, porcelain, and several mineral substances, yielded more or less foreign matter, which was successfully excluded when gold or platinum was substituted; but still, water, which had been redistilled at a low temperature in a silver alembic, did afford acid and alkali; the source of this was next traced to the hands of the operator, and the accidental contact of test-papers, all which were consequently avoided, with a proportionate diminution of the problematical appearances; but they were yet present, for notwithstanding all precautions, litmus was reddened in the positive, and turmeric rendered brown in the negative vessel: it was now, however, found that the acid and alkali were nitric acid and ammonia; substances producible by new arrangements of the elements of air and water; and accordingly when very pure water, carefully deprived, and kept from the contact, of air, was electrized *in vacuo*,

in cones of *gold*, which had not been *handled*, nothing but oxygen and hydrogen were elicited from it.

The question, therefore, concerning the origin of the appearances cited, was now so far satisfactorily determined. He then entered into many valuable contingent inquiries, and proves this essential fact, that electricity has the power not merely of rendering evident the smallest traces of foreign matter, but of decomposing compounds with apparent facility and perfection, the elements of which are held together by the strongest chemical attractive force; whence it was concluded that substances, hitherto deemed simple or elementary, might, under this all-powerful decomposing agent, afford evidence of a compound nature, and yield either known or new elementary bodies. The inquiry was accordingly resumed under this new light; and the Bakerian Lecture, read to the Royal Society, in November, 1807, contains the results to which it led. The first substances which occurred as likely to afford successful and novel information were the fixed alkalis. Upon subjecting caustic potassa to the action of the voltaic pile, it was found not to conduct electricity; and when its aqueous solution was used, the water only appeared to suffer decomposition. After several unsuccessful trials, it was at length found that the alkali, gently breathed upon, became sufficiently moist to suffer the transfer of electricity, and the appearances were very remarkable; effervescence ensued at the positive pole, and, at the negative, there appeared small and brilliant globules of a perfectly metallic appearance, but which presently burned upon exposure to air, and seemed to reproduce the alkali. There now could be little doubt that this matter was the *base* of potassa; but it became necessary to collect and preserve it for examination; and this was a task attended by many serious and apparently insurmountable obstacles, for the globules were successively immersed in a great variety of fluids, upon all of which they had more or less action, and none of which afforded a means of retaining them in a metallic state; at length the fluid called *naphtha* was successfully employed, and in it they were collected and preserved for a considerable time without material alteration. They were found truly metallic, eminently combustible, remarkably light, acting energetically and inflaming upon water, and producing potassa by their union with oxygen. Many of their other properties were also determined; and it here deserves especially to be mentioned, that although *potassium*, for so this new metal was called, was only obtained in minute atoms and a few grains in weight, all its essential properties, as subsequently determined, were correctly and minutely made out. *Sodium* was next obtained from soda by the same new method of decomposition; and shortly after the alkaline earths were shown to contain analogous inflammable and metallic bases. The *Philosophical Transactions* for several subsequent years contain continuations of these inquiries, which were actively and successfully pursued by their author, and which speedily attracting the admiration of the scientific world, induced others to resume and extend them.

In the year 1810 the subject of Sir HUMPHRY'S Bakerian Lecture is the "Oxymuriatic acid and its compounds," a subject which is pursued in several successive communications, abounding in original views and new discoveries. It is in these papers that the true nature of oxymuriatic

acid is demonstrated, that the views of SCHEELE respecting it are established, and that the erroneous reasoning regarding its composition, originating with BERTHOLLET, and sanctioned by the assent of the chemists of Europe, is refuted and subverted. Much acute reasoning, and many specimens of the true logic of the science, are to be found in these details, blended with sound descriptions of new compounds, and new applications of the facts that were developed : it is here that the nature of the muriatic acid is first demonstrated; that oxymuriatic acid (under the new name of *chlorine*) is shown to be an undecomposed substance; that a multiplicity of erroneous views respecting their compounds are corrected, and others established upon the basis of experiment, to the exclusion of hypothetical reasoning. The new theory to which these inquiries led was actively canvassed and opposed; but the objections urged against it necessarily yielded to the sound arguments and unequivocal experiments upon which it was founded, and the fame which the author acquired, by the gradual admission and general adoption of these new modes of reasoning and of research, was scarcely inferior to that which rewarded his more brilliant discovery of the alkaline bases. The several papers which follow this Lecture, and in which, among other subjects, the nature of *fluorine* and of *iodine* are discussed, may be considered as continuations and illustrations of the Bakerian Lecture, and they each contain further proofs of the inventive genius and talent of their author.

DAVY had now established himself as one of the first chemists of Europe: whether we found his claims to that distinction upon the number and importance of his original discoveries, or upon the profundity of his reasoning powers displayed in their applications, and stamping a peculiar character upon his inquiries. About this time he became desirous of embodying the results of his labours, and of displaying them in a more connected and systematic form, and, accordingly, in 1810, he published the first volume of his *Elements of Chemical Philosophy*, a work which, though it bears some marks of hasty composition, is abundant in evidence of the author's talent as an eloquent writer, a clear reasoner, and a shrewd and sagacious experimentalist. It is to be regretted that the second volume of this work never appeared; for although it be true that the first chiefly embraced those parts of the science which had been the particular objects of his successful studies, it cannot be doubted that his genius would have cast a new light upon the department of chemistry with which he was less immediately intimate. His *Elements of Agricultural Chemistry* appeared shortly after the *Chemical Philosophy*; it is a work containing some new and useful facts and views, and is well adapted to the capacities of those whom he intended to instruct.

Sir HUMPHRY had now laid a secure and deep foundation of permanent eminence and imperishable reputation as a chemical philosopher of the first class; but whilst he was thus employed, he was at the same time reaping equally verdant, though less durable laurels, as a lecturer; his style was peculiar and impressive; his eloquence powerful and appropriate; his experiments brilliant and original; his reasoning refined and acute. But to dwell further upon this subject would lead me to biographical particulars respecting his connexion with the Royal Institution,

and to details not immediately belonging to my present object, which I willingly, and, indeed, anxiously avoid, and turn with pleasure to his discovery of the SAFETY-LAMP.

The first paper in relation to this subject is printed in the *Philosophical Transactions* for 1815, and was followed by four communications bearing upon the same inquiry, the last of which was read to the Royal Society in January, 1817. These essays would alone characterize their author as a philosopher of no common stamp. Finding that flame would not recede through tubes of very small diameters, the idea occurred to him of constructing a lamp, the flame of which should have no connexion with the surrounding air, except by capillary tubes; and he inferred, from previous experiments, that such a lamp might safely be employed for the illumination of coal-mines infested with the explosive atmosphere commonly called *fire-damp*. He then endeavoured to ascertain the extent to which the tubes might be shortened without interfering with the principle of safety, and was thus led to cut them down till their transverse section became a series of fine meshes: this so closely resembled *wire-gauze*, that he was induced to try how far that tissue would prevent the passage of flame, and finding it effectual, he employed it in the construction of his lamp, and ultimately adopted the simple and efficient arrangement now in general and successful use. His researches respecting the nature of flame, and the temperatures at which combustion may, under various circumstances, be carried on, are parts of this general inquiry, and are not less ingenious than original.

Sir JOSEPH BANKS, who had been for so many years President of the Royal Society, died in June, 1820, and on the 30th of November following, Sir HUMPHRY DAVY succeeded to that high and honourable office. His *Discourses*, delivered on various occasions before that body, will give a fair idea of the general style of his eloquence and power in oratorical composition. He continued to contribute papers as heretofore, and some of them upon subjects of much interest, ably and philosophically discussed: among them, the essays on the modes of protecting the copper sheathing of ships deserve especial notice*.

In the course of the year 1827, Sir HUMPHRY'S general state of health became much impaired; he passed the greater part of the year 1828 in Italy, and terminated his memorable existence at Geneva, in May, 1829, in the fifty-second year of his age.

Of this eminent and extraordinary person two biographical memoirs have appeared, the one by Dr. PARIS, in 1831; and the other by his brother, Dr. JOHN DAVY, in 1836. Neither of these works will perhaps perfectly satisfy the *scientific* reader: they contain a variety of interesting and important matter, but are scarcely sufficiently ample in reference to those events in Sir HUMPHRY'S life, principally connected with his chemical pursuits, and his philosophical eminence. Dr. DAVY has, however, to a considerable extent filled this chasm in his brother's biography by the recent republication of his *Life*, in the form of a prefatory memoir to Sir HUMPHRY'S collected works. These volumes are a valuable addition to the philosophical literature of Europe, and furnish the chemical reader with a work of reference of great interest and usefulness.

* A list of Sir Humphry Davy's principal publications will be found at the end of Dr. Paris's work.

I became acquainted with Sir H. DAVY very soon after his arrival in London in 1801, having been introduced to him by Mr. HATCHETT, as a boy fond of chemistry: I was at that time at Westminster School, and often stole away upon a half holiday, to pass an occasional hour at the Royal Institution; soon afterwards I went abroad, and as soon as possible after my return, I renewed my acquaintance with Sir HUMPHRY; this acquaintance ripened into the friendship which so long subsisted between us, and which ultimately led to an event of which I shall always be justly proud, that of having been recommended by himself as a proper person to succeed him as Professor of Chemistry in the Royal Institution; to which office, after having delivered a probationary course of lectures during the preceding spring, I was unanimously elected on the 7th of June, 1813. From the time that Sir HUMPHRY quitted England for the Continent, in October, 1813, till his return in 1815, and during his subsequent visit in 1818, till his return in 1820, he regularly corresponded with me; and in the intermediate periods I was almost constantly in the enjoyment of his friendship and his society, or a witness and occasional assistant in his experimental labours in the laboratory of the Royal Institution.

From this correspondence I have selected three letters, which may, I think, be interesting, as relating to some of the points touched upon in the preceding paragraphs:—

My dear Sir,

Paris, December 11, 1813.

I SHALL enclose for the Royal Society a paper, containing results that, I think, will interest you. You will be so good as to give the paper to Sir Joseph as soon as you have perused it. I have sent him a copy, of which this is a duplicate. I wish that it may be read to the Royal Society as soon as possible. I transmit this copy to you, thinking that as you are preparing your Course, you will be glad to make an acquaintance with (iodine) a *fourth* supporter of combustion. Will you have the kindness to inform my brother with the contents of the paper; and request him to use some delicacy in communicating them to Dr. Hope, lest too great a shock should be given to the Professor, in finding the last hopes of oxymuriatic acid destroyed? I am only joking, for I know the Doctor is at the bottom too genuine a lover of science, and of truth, and of order, to preserve an arrangement which will have few advocates three months hence.

I leave Paris in a few days for Auvergne. You can write to me by the Transport Board on any matters of science, the letter being open, and sent under cover to Monsieur le Senateur Comte Real, Bureau de Police, Paris. Kind remembrances to all friends. Lady Davy desires her best compliments.

I am, my dear Sir, very sincerely yours,

Wm. T. Brande, Esq., Secretary to the Royal Society,
Royal Institution, 21, Albemarle Street, London.

H. DAVY.

His next letter is written soon after his arrival in Italy, in 1818*.

* The first paragraph relates to my marriage. I had previously received from him the following note, which I insert as a proof of the kindness of his feelings, and a specimen of his expression of them:

Venice, June 26, 1818.

My dear Sir,—Probably before you receive this letter you will be one of the happiest men in the world. You cannot be happier than I wish you to be: may you long enjoy all the best blessings that life can bestow, and health give relish to.

We have had a very prosperous journey here. The little scientific news there is, I have collected

in a letter to Sir Joseph Banks, which I am sure he will show you, and, therefore, will not tire you with repetitions.

Pray remember me, with the best wishes that can come from a friend, whose wishes are hopes for, and even perfect confidence in, your happiness, to her whom, in my next letter, I hope I shall have authority to call by your name.

I mention Trieste as the place where, if you will be so good as to write to me, I shall be sure of receiving your letter.

I am, my dear Sir,
very sincerely yours,

W. T. Brande, Esq.,
Royal Institution.

H. DAVY.

My dear Sir,

Idria, August 23, 1818.

I HOPE this letter will not arrive before you are not only *benedictus* but *beatus*; for if this word can at all apply to man in this mortal state, it is at such a time, and under such circumstances.

Since I wrote to you, at Vienna, we have made a very long journey. I have visited the most interesting parts of Hungary, Styria, Saltzbourg, and Carinthia, and have seen some mountain scenery quite as worthy of admiration as any I ever saw in the [Swiss Alps. I have lived amongst mountaineers purer and more uncorrupted than even the Swiss. We have had delightful weather, and have had full enjoyment of summer, fine but not sultry, in districts where, without fine weather, there could have been but little pleasure.

I will not write a geological letter, or describe to you the great calcareous mountain-chain that runs from Kevnoud, in Hungary, to Berchtesgarten in Bavaria, and to the centre of Carniola, with its belts of breccia, its intersections of schist, and its central column of granite. * * * * But I will give you a line on the *quicksilver mines*, which I came here to see. The formation is in bituminous schist, which sometimes emits inflammable air, and which alternates with limestone, like the Derbyshire. I have this day been down 1120 feet, and returned without being *salivated*. I pity the poor workmen, who all lose their teeth in a very short time. The veins of cinnabar are very beautiful; and one I saw nearly a foot in thickness. My wife went down with me, and visited the whole mine, which is rather a feat to be talked of for a lady.

I found a good deal of inflammable air (Carburetted Hydrogen) in the great salt-mine at Helstedt; the salt, like the quicksilver here, is in bituminous schist. I taught them the use of the lamp, which, notwithstanding the science of their imperial proprietor, they were still unacquainted with. A good many men had been burned a few months ago. The inflammable air is found in largest quantities where the *blue salt* is. I have been again searching in vain for the cause of this extraordinary colour.

I sent, in a letter to Mr. Hatchett, a little of Professor West's new metal, *Sirium*: I doubt its being a simple substance; perhaps you will try a few experiments upon it. I believe I mentioned to you, in my last letter, Count Stadion's *Oxychloric acid*; a very curious substance, very like sulphuric acid, and containing much more oxygen than Gay Lussac's acid. I have used detonating powder for Rivière's gun, made with the *oxychlorate* of Potassa, to use Stadion's name, and it answers perfectly. I am now in the *Proteus* country, and hope to send Sir Everard Home some alive; I go to the caverns where they are found, the day after tomorrow. I have seen nothing, and heard nothing, from England for two months. Pray address to me, Rome. I shall probably be there by the middle of October, on our way to Naples.

With every kind wish for your happiness, and that of her most dear to you, in which my wife joins me,

I am, my dear Sir, very sincerely yours,

H. DAVY.

Wm. Thos. Brande, Esq., Sec., R.S.

Royal Institution, Albemarle Street, London.

The third letter was written shortly previous to his return to England, and to the death of Sir JOSEPH BANKS, who expired at his villa at Spring Grove, near Isleworth, on the 19th of June, 1820.

Hotel de la Paix, Rue de la Paix, Paris, May 20, 1820.

My dear Sir,

It is long since I have written to you, but unless I have something to communicate, I do not like to trouble my friends; and in Italy, unless I rung changes upon my own small stock of scientific results, I had nothing to state in the way of chemical or philosophical information.

Here, there is little going on which you will not have seen noticed in the journals. A subject which seems to awaken much attention, is the increase of temperature of the surface of the globe, at considerable depths. If the results can be depended on, and are not influenced by accidental causes, the geometricians say they prove that at a few miles below the surface, the interior must be intensely hot; of a tempera-

ture far beyond that produced in any of our artificial operations. The subject is, at all events, a very curious one, and, in its geological relations, worth a very minute investigation.

Lord and Lady Spencer are here, and will be here for some time: they this morning gave me a piece of news which I hope is incorrect, but which makes us all very uneasy: it is that Sir Joseph is going to resign the chair of the Royal Society. * * * * * Pray write me a few lines, to tell me if this be true. Feeling very much interested in the progress of science in Great Britain, and in the dignity of scientific men, and of the Royal Society, I shall deeply regret such a measure, if it be in contemplation, * * * * * From the way in which Lord Spencer expressed himself, I have no doubt he would accept the chair; at the same time, I did not put the question to him, but Lord Spencer, or * * * * * would give dignity to the situation; and scientific *Vice Presidents*, might keep alive the scientific character of the body. * * * * * Pray write to me by return of post upon this subject, which I think is almost a *national one*.

I am much obliged to you for your *Manual*, which is the best collection and arrangement of chemical science existing. I have given the only copy I have received to Sementini, who is going to publish immediately an Italian translation of it. I preferred making it subservient to the progress of science, to keeping it for my own gratification. Lady Davy joins me in kind remembrances to Mrs. Brande.

Believe me to be, my dear sir, very sincerely yours,

Wm. Brande, Esq., Sec. R. S., &c.

H. DAVY.

Royal Institution, Albemarle Street, London.

Of Sir HUMPHRY's latter days, the following particulars are extracted from the interesting narrative of his friend and physician, Dr. TOBIN, who accompanied him on his last journey into Italy, and was with him till his death. Dr. TOBIN says, that on his arrival in London, March 26, 1828, he found Sir HUMPHRY much altered during the four years which had elapsed since he last saw him, and it was evident that although his mind was still vigorous and full of energy, his bodily infirmities pressed heavily upon him. On the morning of the 29th of March, he left his house in Park Street, Grosvenor Square, for Dover, crossed next day to Calais, and then proceeded up the Rhine, and through Styria and Carniola, into Italy. He arrived at Rome on the 18th of November, without any remarkable change in his health. And, as it appears from Dr. TOBIN's narrative, that he frequently was occupied during the greater part of the day in fly-fishing and shooting, his corporeal strength must have been considerable. He, however, shunned society, and passed his evenings, and such days as he kept the house, in being read to, and in playing at *écarté*, and in dictating his *Vision*. In his diary, for instance, on the 31st of December, 1828, Dr. TOBIN says, "Our daily life has hitherto been as monotonous as possible. Sir Humphry sees no society, and wishes to see none, and his only pleasure and amusement seems to consist in shooting. He drives out every day in the surrounding *Campagna*, often to a distance of twelve and fourteen miles from Rome, when he gets out, and rides on his pony over the fields in search of quails or snipes. On his return, when he is not too much fatigued, he dictates to me a continuation of his *Vision*, which he thinks of forming into a series of dialogues on religion and other subjects; and our evenings are spent as they have been ever since we left Calais, with a game or two at cards, and with my reading to him different works, principally English and French, which he procures from a circulating library in the Corso. I have formed no acquaintances, as Sir Humphry wishes me not to do so;

but when I have copied off the morning's dictation, I often take a solitary walk in the garden of the Pincio, to St. Peter's, or to the Colosseum."—(TOBIN'S *Journal*, p. 196.)

On the 20th of February, 1829, Sir H. DAVY was attacked with a renewed stroke of palsy*, which had nearly proved fatal, and which induced Dr. TOBIN to write to Dr. DAVY at Malta, and to Lady DAVY in London; the former arrived at Rome on the 15th of March, and the latter on the 30th. By this time Sir HUMPHRY had considerably regained the power over his limbs, and was able to lie upon the sofa the greater part of the day. "It seems impossible," says Dr. TOBIN, "for him to exist without being read to, and on one day I read Shakspeare to him for *nine* hours."

On the 30th of April, Sir HUMPHRY, now accompanied by his wife and brother, left Rome, and passing through Sienna, Florence, Genoa, and Turin, over Mount Cenis, reached Geneva on the 28th of May; on the 29th, the following is recorded in Dr. TOBIN'S *Diary*. "I quitted Sir Humphry yesterday evening, after having read to him as usual till about ten o'clock. Our book was Smollett's *Humphrey Clinker*, and little did I think it was the last book he would ever listen to. He seemed in tolerable spirits, but upon going to bed was seized with spasms, which, however, were not violent, and soon ceased. I left him when in bed, and bidding me "good night," he said I should see him better in the morning. Lady Davy and the Doctor also quitted him, and George (his servant) went to bed in his master's room, as he always had done since Sir Humphry's illness at Rome. At six o'clock this morning, Lady Davy's man-servant came to my room, and told me that Sir Humphry was no more! I replied that it was impossible, and that he probably only lay in a torpor; but I went down to his room instantly, when I found that the servant's words were, alas! but too true. I asked George why he had not called me, when he said, that he had sent up, but now found that it had been to a wrong room. He told me that Sir Humphry went to sleep after we had left him, but that he twice waked, and that at half-past one, hearing him get out of bed, he went to him, when Sir Humphry said he did not want his assistance, and poured some solution of acetate of morphine into a wine-glass of water; but this still remained untouched upon his table. George then helped him into bed, where, he says, he lay quite still till a little after two o'clock, when hearing him groan, he went to him, and found that he was senseless and expiring. He instantly called up Lady Davy and the Doctor, and sent up, as he believed, to me; but Sir Humphry, he says, never spoke again, and expired without a sigh.

"I had so often, whilst at Rome, seen Sir Humphry lie for hours together in a state of torpor, and to all appearance dead, that it was

* The first symptoms of this disease seem to have alarmed him in the year 1826, and to have appeared after his exertions on the 30th of November in that year, on which occasion he delivered his last discourse, at the anniversary meeting of the Royal Society; and some weeks afterwards, whilst upon a shooting excursion with Lord Gage, in Sussex, he was seized with a more alarming attack, from the immediate effects of which he however soon rallied.

difficult for me to persuade myself of the truth; but the delusion at length vanished, and it became too evident that all that remained before me of this great philosopher, was merely the cold and senseless frame with which he had worked. The animating spirit had fled to its oft self-imagined planetary world, there to join the rejoicing souls of the great and good of past ages, soaring from system to system, and with them still to do good in a higher and less bounded sphere, and I knew that it was freed from many a wearisome and painful toil. Yet I could not look upon Sir Humphry as he was, without remembering that which he had been, and my tears would fall, spite of my effort to restrain them."

The following memorandum, relating to the last hours of his brother's life, is given by Dr. DAVY, (*Memoirs*, vol. ii., p. 365.) "On the 28th of May, 1829, we arrived at Geneva: at five, he dined at table and made a tolerable dinner; after dinner he was read to, according to custom. At nine o'clock, he proposed to go to bed. In undressing, he struck his elbow against the projecting arm of the sofa on which he sat: the effect was very extraordinary; he was suddenly seized with an universal tremor; he experienced intense pain in the part struck, and a sensation, he said, as if he were dying. He was got into bed as soon as possible. The painful sensations quickly subsided, and in a few minutes were entirely gone. There was no mark of hurt on the elbow, no pain, or remaining tenderness; and the effect of the blow perplexed him no less than it did me: a slight feverish feeling followed, which he thought little of; he took an anodyne draught of acetate of morphia, and then desired to be read to, that he might be composed to sleep by agreeable images.

"About half-past nine he wished to be left alone, and I took my leave of him for the night, and for ever on earth. His servant, who always slept in his room, called me about half-past two, saying he was taken very ill. I went to him immediately; he was then in a state of insensibility; his respiration extremely slow and convulsive, and the pulse imperceptible: he was dying; and in a few minutes he expired. I thank God I was present to close his eyes. In death, his countenance was composed, and of its mildest expression, indicative of no pain or suffering in the separation of the immortal from the mortal part. This fatal moment was about three, A.M., on the 29th of May." His remains were deposited on the 1st of June in the burying-ground, without the walls of Geneva, and close to the grave of Professor PICTET.

The theory of definite proportionals was adopted and illustrated by Sir H. DAVY, and his *Elements* is the first publication in which it was generally applied. This theory received, about the same time, extensive elucidation at the hands of M. GAY LUSSAC, but its promulgation in this country is chiefly to be attributed to Dr. WOLLASTON, whose admirable suggestion of a synoptic scale of chemical equivalents, already referred to, was brought before the Royal Society in November, 1813. Many years previous to this he had established the important doctrine of multiple proportions, in a paper "On Super-acid and Sub-acid Salts," printed in the *Philosophical Transactions* for the year 1808: he now showed the important practical applications of which the theory was susceptible, and

by connecting the scale of equivalents with GUNTER'S sliding rule, has put into the hands of the chemist an instrument infinite in its uses, and equally essential to the student, the adept, and the manufacturer.

Dr. WOLLASTON'S first contribution to the Transactions of the Royal Society was in June, 1797, being an essay *On Gouty and Urinous Concretions*, in which he made known several new compounds connected with the production of those maladies, in addition to the uric combinations previously discovered by SCHEELE: these were, Phosphate of Lime; Ammonia-magnesian Phosphate; a mixture of the two forming the *fusible Calculus*; Oxalate of Lime; and, more lately, he added Cystic Oxide to the list of his previous discoveries. (*Phil. Trans.*, 1810.) In 1804 and 1805, he made known Palladium and Rhodium, two new metals contained in the ore of platinum, and associated with Osmium and Iridium, discovered about the same time by Mr. TENNANT. In 1809, he showed that the supposed new metal, Tantalum, was identical with Columbium, previously discovered by Mr. HATCHETT; and shortly before his death, which happened on the 22d of December, 1828, in the sixty-third year of his age, he transmitted to the Royal Society the *Bakerian Lecture*, in which he fully describes his ingenious method of rendering platinum malleable.

Dr. WOLLASTON made a few other chemical communications to the Royal Society, but his papers are chiefly on subjects more immediately connected with physical and physiological inquiries; they are all remarkable for the singular and satisfactory simplicity of his experimental methods, for the perspicuity of his theoretical deductions, and for the extreme caution with which he touches upon generalizations and hypothesis. His uncommon tact, neatness, and dexterity as an experimental chemist, will never be forgotten by those who had an opportunity of witnessing his performance of any analytical operation; he practised a peculiar method of microscopic research, in which he willingly instructed those who asked his information; and we owe to him numerous abbreviations of tedious processes, and a variety of improvements in the application of tests, which have gradually become public property, although he never could be induced to describe his manipulations in print, or to communicate to the world his happy and peculiar contrivances.

Of Dr. WOLLASTON, (who was born at East Dereham, in Norfolk, on the sixth of August, 1766,) I am afraid no authentic biography has as yet appeared: the following are a few memoranda respecting his last illness, which were obtained from conversation, at the time, with some of his intimate friends.

In October, 1827, while accompanying a friend to Cashibury, the seat of the Earl of Essex, he spoke of a numbness which he had for some time felt in his left arm, and which he stated he considered as a symptom of paralysis, a disease to which his father and eldest brother had fallen victims, and of which, at a subsequent period, another brother also died. In June, 1828, while on a fishing excursion at Stockbridge, feeling some stronger premonitory indications of a paralytic seizure, he abruptly quitted his amusement, and returned to London. In July of the same year, while on a visit to the late Earl Spencer, at the Isle of Wight, he noticed that a part of the retina of his left eye had become insensible to the

action of light. In the month of September, he went upon a shooting excursion to Mr. WHITBREAD's in Bedfordshire, where he remained eight days, and enjoyed his sport: one evening he jokingly said, "For the first time in my life I count my game by the quarter of a hundred," having killed twenty-five head. He returned home better in health, but soon after, the sensation in his arm became worse, and whilst staying with Mr. BLAKE in Hertfordshire, he felt so unwell and uncomfortable as to be obliged to return home a day or two earlier than he intended. In the course of the following week, symptoms more decidedly alarming came on; the use of his arm was much impaired, and the muscles of the face and organs of speech were affected: his mental faculties, however, remained entire to the last. He was sedulously attended by several medical friends, and especially by Dr. JAMES SOMERVILLE, who remained in the house during his illness and until his death.

The loss of two such men as WOLLASTON and DAVY, within so short a period, and scarcely beyond the prime of life, was a serious national calamity: the sketch which I have given of their labours is a most imperfect outline; but it would have been improper and indecorous to have dismissed this brief History of Chemistry without such notice, and I shall conclude with the following delineation of their intellectual portraits, for which we are indebted to the late Dr. HENRY. (*Elem. of Chem.*, 11th edit., viii.)

"To those high gifts of nature, which are the characteristics of genius, and which constitute its very essence, both those eminent men united an unwearied industry and zeal in research, and habits of accurate reasoning, without which even the energies of genius are inadequate to the achievement of great scientific designs. With these excellencies, common to both, they were nevertheless distinguishable by marked intellectual peculiarities. Bold, ardent, and enthusiastic, DAVY soared to greater heights; he commanded a wider horizon; and his keen vision penetrated to its utmost boundaries. His imagination, in the highest degree fertile and inventive, took a rapid and extensive range in pursuit of conjectural analogies, which he submitted to close and patient comparison with known facts, and tried by an appeal to ingenious and conclusive experiments. He was imbued with the spirit, and was a master in the practice, of the inductive logic; and he has left us some of the noblest examples of the efficacy of that great instrument of human reason in the discovery of truth. He applied it, not only to connect classes of facts of more limited extent and importance, but to develop great and comprehensive laws, which embrace phenomena that are almost universal to the natural world. In explaining those laws, he cast upon them the illumination of his own clear and vivid conceptions;—he felt an intense admiration of the beauty, order, and harmony, which are conspicuous in the perfect CHEMISTRY of NATURE;—and he expressed those feelings with a force of eloquence, which could issue only from a mind of the highest powers, and of the finest sensibilities. With much less enthusiasm from temperament, Dr. WOLLASTON was endowed with bodily senses of extraordinary acuteness and accuracy, and with great general vigour of understanding. Trained in the discipline of the exact sciences, he had acquired a powerful command over his attention, and had habituated himself to the most rigid correct-

ness, both of thought and language. He was sufficiently provided with the resources of the mathematics, to be enabled to pursue, with success, profound inquiries in mechanical and optical philosophy, the results of which enabled him to unfold the causes of phenomena, not before understood, and to enrich the arts, connected with those sciences, by the invention of ingenious and valuable instruments. In Chemistry, he was distinguished by the extreme nicety and delicacy of his observations; by the quickness and precision with which he marked resemblances, and discriminated differences; the sagacity with which he devised experiments, and anticipated their results; and the skill with which he executed the analysis of fragments of new substances, often so minute as to be scarcely perceptible by ordinary eyes. He was remarkable, too, for the caution, with which he advanced from facts to general conclusions; a caution which, if it sometimes prevented him from reaching at once to the most sublime truths, yet rendered every step of his ascent a secure station, from which it was easy to rise to higher and more enlarged inductions."

The talented author of the preceding paragraph is himself now amongst those who claim a place in this historical outline of the progress of chemical philosophy. In the address delivered at the Anniversary Meeting of the Royal Society, on the 30th November, 1836, the President says, "The last name which occurs in the melancholy list of our departed associates is that of Dr. WILLIAM HENRY, to whom the science of Chemistry generally, and of Gaseous Chemistry in particular, is under great obligations. He was the author of nine papers in our *Transactions*, many of them of great merit; and his *Elements of Chemistry* is one of the best-written and best-arranged compendiums of that important and extensive science which has been published of late years, whether in our own or in any other language. The *Memoirs* of the Manchester Society are chiefly indebted to him, in conjunction with Dr. DALTON, for the high character which they have so long maintained. Dr. HENRY, like Dr. WOLLASTON, made the results of science, obtained by the most original and difficult researches, the foundation of a splendid fortune; and few persons have contributed more effectually by their discoveries and exertions to the promotion of those arts and manufactures which form the foundation of the prosperity of a great commercial nation."

The chemical world has also sustained a serious loss in the death of Professor TURNER, of University College in this Metropolis. "Dr. EDWARD TURNER was a native of Jamaica, and studied medicine at Edinburgh, and chemistry at Göttingen, under the instructions of the celebrated analytic chemist, Stromeyer. He became a lecturer on chemistry at Edinburgh in 1824, and his first publication was a short introduction to the study of the laws of chemical combination and the atomic theory. He obtained the Professorship of Chemistry in University College, London, at its first establishment in 1828, a situation which he continued to hold to the end of his life. His *Elements of Chemistry* have enjoyed an uncommon degree of popularity, and are remarkable for clearness and precision, both in the description of his experiments and in the deduction of his theory. He was the author of two papers in the *Philosophical Transactions*, the first, "on the Composition of Chloride of Barium," and the second, containing "Researches on Atomic Weights," both written with

a view of impugning the theory, which had been promulgated by some English chemists of high authority, "that all atomic weights are simple multiples of that of hydrogen." In the year 1835, Dr. TURNER was compelled by the declining state of his health to suspend all original researches, confining himself simply to the duties of his Professorship, and he died in February, 1837, in the fortieth year of his age, to the deep regret of every friend of the progress of chemical science. He was a person of engaging manners and appearance, and of most amiable character; his body was followed to the grave with every manifestation of respect and affectionate attachment by the whole of the pupils and Professors of the Institution, of which he had so long been a principal ornament*."

* The above notice is extracted from the Anniversary Address of the President of the Royal Society on the 30th November, 1837. I had the pleasure of Dr. Turner's acquaintance, and can bear ample testimony to his excellence as a

man, and to his talent and industry as a teacher. Reference need only be made to his elementary work on Chemical Philosophy, to establish his merit as an author.

MANUAL OF CHEMISTRY.

CHAPTER I.

HOMOGENEOUS ATTRACTION. CRYSTALLIZATION.

It is the object of Chemistry to investigate the causes and effects of all changes in the constitution of matter, whether produced by heat, mixture, or other means. Its general range, therefore, is so extensive, and the individual cases requiring explanation so numerous, that *Arrangement* is of the utmost consequence to its successful study. In the present state of our knowledge, it will be found most convenient to begin with the discussions relating to the *general powers or properties of matter*, and afterwards to proceed to the examination of *individual substances*, and to the phenomena which they offer when presented to each other under circumstances favourable to the exertion of their mutual chemical agencies.

The powers and properties of matter, connected with chemical changes, may be considered under the heads of Homogeneous Attraction, or Aggregation; Heat; Light; Chemical Attraction, or Affinity; Electricity, and Magnetism.

§ 1.—ATTRACTION. AGGREGATION. CRYSTALLIZATION.

ATTRACTION may be regarded as acting at *sensible* and at *insensible* distances. In the former case, it is called *gravitation*. It is the power by which substances are propelled towards the earth; it exists in all known forms of matter; and it acts directly as the mass, and inversely as the square of the distance: restrained by *inertia*, it preserves the planetary bodies in their orbits, presides over their movements, and tends to confer upon the system of the universe that consummate harmony which the genius of Newton unveiled.

Attraction is also exerted at insensible distances, and among the minutest atoms of matter. It thus preserves the form, and modifies the texture of solids; gives a spherical figure to fluids; causes the adhesion of surfaces; and influences the mechanical characters of bodies. The different forces with which it is exerted are seen in the different *textures* of solid bodies, which are sometimes exceedingly hard and difficultly divisible, as the diamond, rock-crystal, &c. others are comparatively soft or brittle, and exhibit less intensity of aggregation, such as chalk and calcareous spar: and in others the power is so modified as to produce plasticity, porosity, elasticity, and tenacity, as seen in clay, sponge, caoutchouc, and iron wire.

As the results of gravitation are counteracted by those of inertia, so the influence of aggregation is opposed by a repulsive force, apparently due to the various agencies of *heat*; and it is probable that the various states or forms of matter are chiefly dependent upon the relative intensities of these antagonist forces. In *solids* aggregation predominates so as to prevent their particles freely moving upon each other; but in fluids they move upon each other with the utmost ease, and in some more readily than in others; hence their division into *liquids* or *inelastic fluids*, and *aëriform* or *elastic fluids*; the dimensions of the former are not materially influenced by pressure, and they were for a long time considered as absolutely incompressible; this, however, is not strictly true, although the force required to change their volume is very great, and the extent of the change very small. The following table shows the amount of compression of four liquids, deduced from the experiments of Oersted, in millionths of their volume, for each additional atmosphere.

Mercury	2.65	millionth parts.
Alcohol	21.65	"
Water	46.65	"
Ether	61.65	"

Mr. Daniell states that by plunging a vessel of water into the sea to a depth of 1000 fathoms, the compression amounts to one-twentieth of the bulk. In all cases after the pressure is withdrawn, the liquids reassume their original bulks. Aëriform or elastic fluids are indefinitely elastic and compressible, their volume, as was first accurately ascertained by Mariotte, being always inversely as the pressure. (See ATMOSPHERIC AIR.) The influences of *heat* upon the forms of matter will be fully discussed in the section upon that subject.

The mutual attraction between the surfaces of solids and liquids gives rise to the phenomena of *capillary attraction*, so called from its causing the visible rise of fluids in tubes of very small bore: thus, if a tube, with a capillary bore of one-fiftieth of an inch, be dipped at one end into a glass of water, the water rises to about $2\frac{1}{2}$ inches, and the rise is great in proportion to the smallness of the bore of the tube. If two plates of glass be so held as to form a very acute angle with each other, and the lower edges dipped into water, the liquid rises in the form of a curve (hyperbola) between the plates, rising highest where the space between them is least. It is in consequence of this species of attraction that a drop of water pressed upon a solid surface wets and adheres to it; and that the surface of the water in a tumbler is not truly level, but a little elevated upon the edges. These phenomena of capillary action depend upon the nature of the substances presented to each other; thus the water will not rise upon greasy glass, or wax; and hence also different liquids rise to different heights in the same tube, independent of their specific gravities, and of their relative degrees of viscosity; and mercury not only does not rise, but is depressed in the bore of a common glass tube: so that, unlike water, it presents a convex instead of a concave surface when poured into a glass, because in it the attraction of the particles of the mercury for each other is great, and they are not attracted by those of the glass; in other words, they are incapable of *wetting* it. "The mercury within the tube is cut off by the inactive surface of the

glass from the homogenous attraction of the surrounding mass; its own self-attractive force therefore acts as from its centre, drawing its particles together and causing them to assume more or less of a globular aggregation, according to the same law which determines the spheroidal form of a suspended drop of liquid."—See DANIELL'S *Introd.* 583. The rising of fluids in porous and spongy bodies, the ascent of oil or spirit in the wicks of lamps, the diffusion of moisture in the earth, and the distribution of the juices of plants, are a few of the important consequences of capillary attraction.

Mr. Daniell remarks, that the same adhesive attraction takes place also between solids and aëriform bodies, as illustrated by the following experiments. Sift some magnesia upon the surface of water, and it will presently sink to the bottom; sift in the same way some fine iron filings, and although their specific gravity is nearly four times greater than that of magnesia, and between seven and eight times greater than that of water, they float upon the surface and to such an extent, that a stratum of considerable thickness may be laid on the liquid; this at length sinks in considerable masses, when it is seen that they had been previously buoyed up by the adhesion of air, which their accumulated weight even carries with them to the bottom, the surface of each fragment of metal having been enfilmed with air, which prevented its being wetted by the water: in the case of the magnesia its attraction for air being less, it was more easily displaced by the water. The force of adhesion of air to glass has also been shown by Mr. Daniell to be very considerable, and to this cause he refers the gradual deterioration of barometers, by the creeping up of air between the mercury and the tube, an effect which he has ingeniously prevented by welding a ring of platinum to the bottom of the tube, which admits of the adhesion of, or being *wetted* by, the mercury, and so intercepts the air. The welding of the platinum to the hot glass is, he observes, a good instance of strong heterogeneous attraction.—(*Introd.* § 87.)

The adhesion of air to a liquid is shown by the quantity which escapes when water is poured from one vessel into another, the air attached to its surface being carried down by the momentum of the falling mass and again escaping in bubbles: the foam of water-falls results from the same cause, and it is thus that air gradually pervades masses of water, and tends to its entire aëration, so as to fit it for the respiration of aquatic animals. This air escapes under diminished pressure, and may be entirely expelled by long continued boiling. Many other phenomena connected with this subject will afterwards come before us.

The results of attraction, as relating to the shape and form of matter, are influenced by the circumstances under which it has taken place. Sometimes the particles are, as it were, indiscriminately collected: at others, they are beautifully arranged, producing regular and determinate figures; in this case, bodies of the same composition often affect the same form; hence we are not unfrequently enabled to infer the composition of a substance from accurate inspection of its external or mechanical characters. Absolute identity of form, however, is not necessarily associated with identity of composition, for certain substances may be substituted for each other in combination, without affecting the form of the com-

pound. Thus the arseniate and binarsenate of soda have the same forms as the phosphate and biphosphate of soda; and the arseniate and binarsenate of ammonia resemble the phosphate and biphosphate of that alkali. Professor Mitscherlich, (*Ann. de Chimie et Phys.*, tom. xiv. xix. xxiv.) to whom we owe these and other facts connected with the subject, which we shall consider afterwards, terms such salts *isomorphous*, and has shown that there is a remarkable analogy in the chemical arrangement of their constituents. Thus, in the above instances, the proportionals of acid, of base, and of water of crystallization, correspond; and he has traced a similar correspondence in the atomic constitution of the acids of the salts.

The regular polyhedral solids resulting from homogeneous attraction are usually called *crystals*; and the bodies are said to be susceptible of *crystallization*. To enable the particles of bodies to assume that regular form which crystals exhibit, it is obvious that they must have freedom of motion; and, accordingly, the first step towards obtaining a body in its crystalline form, is generally to confer upon it either the liquid or aëri-form state. The former is usually effected by solution in water, alcohol, or other liquids; the latter by exposure to heat.

When common salt is dissolved in water, its particles may be regarded as disposed at regular distances throughout the fluid; and if the quantity of water be considerable, the particles will be too far asunder to exert reciprocal attraction: in other words, they will be more powerfully attracted by the water than by each other. If we now slowly get rid of a portion of the water by evaporation, some of the saline particles will gradually approach each other, and they will aggregate according to certain laws, producing a regular solid of a *cubic form*; another portion of the salt will remain dissolved in the residuary water, which is usually called the *mother liquor* or *water*.

1

2

When crystallized substances are slowly acted upon by water, its influence is often curiously modified by the texture of the saline mass, (Daniell, *Quart. Journ.*, I.) If for instance, we take a shapeless lump of alum, and plunge it into a tumbler-ful of cold water, we shall observe that in a few days the surface of that salt will be eaten and carved out into a variety of regular forms, somewhat as represented in the annexed cut. If we now put a drop of the solution contained in the tumbler upon a plate of glass, we shall perceive, as the water slowly evaporates, that the particles of alum which it contained congregate into regular forms, which, when examined by a common pocket lens, appear as in fig. 2, and are small and beautifully formed eight-sided figures, or *octoëdra*. In this case the water is said to be the *solvent* of the alum, and the process by which it is obtained in regular forms or *crystals*, is called *crystallization*. In this

and similar instances, the crystals are liable to certain *modifications*; thus, among the little octoëdrons, to which we have adverted, it is not uncommon to find some, the angles of which are cut off, or *truncated*, or replaced by secondary surfaces; sometimes the edges too are similarly modified, and the crystals assume these figures:

Truncated Angles.

Truncated Edges.

Truncated Edges and Angles.

Most of the saline substances soluble in water may be thus exhibited in a crystalline form; and as each substance usually assumes a distinct figure, or is characterized by some obvious, and, at the same time, peculiar properties, we are often enabled to pronounce upon the chemical nature or composition of a body, by a careful examination of its crystalline forms; and such experiments are particularly neat and satisfactory, in consequence of their facility, and the small scale upon which they may be performed: for the figures of the smallest crystals obtained from a drop of their solution, resemble the large ones formed in gallons of it; and although, in collecting specimens of crystallized salts, it is convenient to have them large and perfect, the smallest ones that may be viewed through a microscope furnish the chemist with equally satisfactory evidence of the nature of the dissolved salt: for instance, put a tea-spoonful of common salt, nitre, Glauber's salt, and Epsom salt, into separate wine glasses: fill them up with water, and occasionally stir their contents to help the solution: when dissolved take a drop of the clear liquor, with a glass rod, out of each of the wine-glasses, and place them side by side upon a strip of clean plate-glass, which may be placed upon a chimney-piece, or somewhere very gently warmed. As the water evaporates, the salts will crystallize, and we shall observe the following figures appropriated to each: the common salt exhibits *cubes*; the Epsom salt, *four-sided prisms*; the nitre, *six-sided prisms*; the Glauber's salt, *striated six-sided prisms*.

Common Salt.

Epsom Salt.

Nitre.

Glauber's Salt.

The Glauber's salt and the nitre might possibly at first be mistaken for each other, but, while the latter remains unaltered by exposure to air, the former soon loses its transparency, and crumbles down into white powder. Salts which behave thus are said to *effloresce**: other salts,

* This property of efflorescence would appear in some cases to depend upon superficial fracture, for Mr. Faraday found that crystals of carbonate, phosphate, and sulphate of soda, having no parts of their surfaces broken, and carefully preserved from external violence, remained perfect; but upon breaking or scratching their surface efflorescence began at that part, and covered the whole.—*Phil. Trs.*, 1834, p. 74.

instead of thus spontaneously parting with a portion of their *water of crystallization*, attract moisture from the air, or *deliquesce*, as is the case with carbonate of potassa, acetate of potassa, chloride of calcium, &c.: alum and many other salts, although they contain water, do not thus part with it, and are *permanent* in the air. But water is not necessarily contained in all crystals: there is none, for instance, in nitre; and such are called *anhydrous salts**. Some salts require a high temperature to deprive them of water. This is the case with gypsum, or sulphate of lime, which is commonly found in large transparent crystals, permanent in the air; but at a red heat they lose one-fifth their weight of water, and crumble down into the white powder commonly called *plaster of Paris*, which is, therefore, an *anhydrous* sulphate of lime, and which, when mixed with a little water, again combines with it, and concretes in the act of combination; hence the use of this substance for forming casts or impressions, as seen in mouldings, busts, &c. Efflorescent salts may sometimes be conveniently preserved by slightly oiling their surfaces, or by soaking them for a few hours in olive oil, and then wiping them and putting them in bottles; or they may be kept under a glass shade in which is also included a small saucer of water. The action of heat upon salts is much influenced by their relative quantities of water of crystallization; it renders some of them, such as sulphate of soda, extremely fusible; from others the water evaporates before fusion, and occasions the efflorescence of the salt; and if contained in their pores, it causes them to *decrepitate*, or fly to pieces when heated, with a peculiar crackling; but this effect more generally depends upon the sudden expansion of the outer crust of the crystal, and its bad conducting power for heat.

10

Epsom Salt, or Sulphate of Magnesia.

11

Saltpetre, or Nitrate of Potassa.

The regularity of the figures of crystals will be influenced by the rapidity of the evaporation; if the process be slowly conducted, the particles unite with great regularity; if hurried, the crystals are irregular and confused. Loaf-sugar and sugar-candy furnish good instances of such modifications. The former being the result of rapid, the latter of slow, crystallization. In common cases, the evaporation may be continued till a *pellicle* forms upon the surface of the solution, which indicates that the attraction of the saline particles for each other is becoming superior to their attraction for the water. The formation,

* *Anhydrous* is a term derived from the Greek, signifying *without water*.

therefore, of a superficial pellicle is the common criterion of the fitness of a solution for crystallization; but where the object is to obtain very regular and very large crystals, the evaporation must be much slower, and carried to much less extent; even *spontaneous evaporation*, or that which takes place at common temperatures, must be resorted to.

It is in this way that the gigantic crystals of sulphate of magnesia and of nitrate of potassa, represented in figs. 10 and 11, were procured; they are here inserted to show the size and perfection of crystals thus slowly deposited in large quantities of their solutions, as contrasted with the microscopic forms described above.

There are certain bodies which may be dissolved or liquified by heat, and, during slow cooling, may be made to crystallize. This is the case with many of the metals; and among them bismuth furnishes, when carefully managed, the most beautiful results; for this purpose a few pounds of it should be melted in a deep iron ladle or crucible, and, as soon as the surface has concentered, it should be punctured with a pointed iron rod, and the liquid metal immediately poured out from the interior; on cautiously breaking the hollow ingot thus obtained, the interior cavity will be found lined with dissected cubical crystals, fig. 12. *Sulphur* may be artificially crystallized by a similar process, and furnishes beautiful heaps of delicate prisms. The masses of crystallized *spermaceti*, often exhibited in shop windows, are obtained in the same way; and it is probable that the cavities in rocks and veins, bearing marks of igneous fusion, and often lined with magnificent specimens of crystalline minerals, owe their origin to some analogous process.

Crystallization of Bismuth.

There is another way of showing the crystalline texture of metals, which, with some of them, answers very well. It consists in washing over a thin plate of the metal with some acid which acts upon its surface. If tinfoil or tin-plate be thus washed over with dilute nitro-muriatic acid, the crystallization of the tin is often rendered beautifully manifest: this has been applied to ornamental purposes, under the name of *moirée metallique*, and different colours are easily given to the reflecting surface of the metal by the application of transparent varnishes.—(See TIN for more full details of this process). Mr. Daniell also developed the crystalline texture of several of the metals by steeping masses of them in acids, by which their surfaces were carved out like the alum in water: and the crystalline structure of a bar of tin was beautifully shown by placing it horizontally in mercury and turning it frequently upon its different faces so as to insure uniformity of action; in about twenty-four hours fissures appear along its lateral and terminal edges which, by gradually splitting, resolve the bar into four equal trihedral rectangular prisms, which, as well as two pyramids from their extremities, may be separated from each other by the point of a knife: it is indifferent to this result whether the square form be given to the bar by casting, hammering, or the filing down of any

other shape. Mr. Daniell further observes, in reference to this development of crystalline architecture, that "if a large crystal of sulphuret of antimony be introduced into a portion of fused sulphuret, and the heat be moderately continued, it will begin to melt down; but so far from this taking place uniformly at the surface, crystals will sometimes be left projecting half an inch from it; and in other places the cavities left by fused crystals will be so large and have such perfect surfaces that their angles may readily be ascertained. In order to observe these phenomena it is only necessary to remove the half-fused piece of sulphuret from its hot bath and allow it to cool."

When bodies are raised in vapour, and this is again condensed into the *solid* state, the process is generally called *sublimation*, and is not uncommonly resorted to to obtain such volatile matters in the form of crystals. The appearance of *camphor*, when thus slowly sublimed, is often extremely beautiful; so also that of *Benzoic acid*. *Iodine* is another body well calculated for the experiment: put a little of it into a clean Florence flask, and gently heat it; it will presently be converted into a deep violet vapour, which, subliming to the cold parts of the vessel, will there condense in small brilliant crystals of octoëdral and rhomboidal figures. There is a substance called *Naphthalin*, obtained during the distillation of coal-tar, and which may commonly be procured at gas-works: when pure, it is white and crystalline, and, if heated in a large phial or flask, its vapour congeals in lamellar crystals of extreme tenuity, crossing each other in all directions, and exhibiting a very singular appearance. *Calomel* and *corrosive sublimate* may be crystallized by a similar process, but the temperature required for their sublimation is considerable; and good crystals can only be obtained by operating upon large quantities, and subliming them very slowly. When flakes of *snow* are examined, they are found to be a congeries of crystals of ice produced by the cooling of the vapour of water.

Some substances are so easily decomposed by heat, and at the same time retain water with such avidity, that it is impossible to crystallize them by any of the above processes: in these cases, crystallization may sometimes be effected by placing the solution under the exhausted receiver of an air-pump, over a surface of sulphuric acid, which, by absorbing the vapour as it rises, causes rapid evaporation at a low temperature.

Some salts may be brought to crystallize by the addition of substances having a strong affinity for water, by which its attraction for the dissolved matters is weakened: thus alcohol, added to certain aqueous saline solutions, produces a separation of crystals, but they are generally small and indistinct.

When two salts of different solubilities are present in the same solution, they often may be separated by crystallization, that which is least soluble constituting the earlier crop of crystals. This method, however, is frequently ineffectual, especially with isomorphous salts, and with such as form triple combinations. When the *sulphates of iron* and *copper* are in solution together, crystals may be obtained of the same form as those of sulphate of iron, but containing variable proportions of sulphate of copper: in the same way the *sulphates of zinc* and *manganese*, and of

magnesia and *manganese*, crystallize together. In all these cases an atomic analogy prevails in the composition of the salts. The formation of *triple salts* is also a common occurrence: a familiar instance is afforded by the *tartrates of potassa and of soda*, the solutions of which, when mixed and evaporated, yield a crop of distinct triple crystals.

Crystallization is accelerated by introducing into the solution a *nucleus*, or solid body, upon which the process begins; and manufacturers often avail themselves of this circumstance. Thus we see *sugar-candy* crystallized upon strings, and *verdigris* upon sticks. There are cases in which it is particularly advantageous to put a few crystals of the dissolved salt into the solution, which soon cause a crop of fresh crystals. And if, for this purpose, we select very perfect forms, they will increase in size as the evaporation proceeds, and being daily turned, so that all sides may receive increments of solid matter in succession, they often produce large crystals of great perfection; but, in proceeding thus, care must be taken not to elevate the temperature of the solution, for if it be raised only a few degrees, portions of the newly-formed crystals are generally redissolved. "Dr. Wollaston made a remark upon the spontaneous growth of large crystals at the expense of small ones in the same solution, exposed to changes of temperature, which illustrates in a beautiful manner, the alternate ascendancy of the two antagonist forces. When the temperature rose the solvent power of the liquid was increased, and some of the solid matter of the crystals was abstracted; but when the temperature again fell this was deposited in a greater proportion upon the larger masses than upon the smaller, so that the latter were in the end entirely taken up and deposited upon the former."—(DANIELL, §. 106.) In some instances, if there be two salts in solution, that will most readily separate of which the crystals have been introduced. Thus, if we dissolve two parts of nitre and three of sulphate of soda in five of warm water, and fill two bottles with the solution, putting into one a crystal of nitre, and into the other a crystal of sulphate of soda, and placing both in ice-cold water, nitre only will crystallize in the one, and sulphate of soda in the other.

A strong saline solution, excluded from the *air*, will frequently crystallize the instant that air is admitted. For this purpose a strong solution of sulphate of soda (3 lbs. of the crystallized salt, to 2 lbs. of water) may be most conveniently used: it should be poured whilst hot into a flask, and tied over with bladder, or secured by a good cork: when cold it remains liquid, but on perforating the bladder, or withdrawing the cork, it gradually shoots from the surface downwards, into a fibrous mass of crystals. This phenomenon has been unsatisfactorily referred to atmospheric pressure. (GAY LUSSAC, *Ann. de Chim.*, vol. lxxxvii.) Mr. Graham (*Edinb. Phil. Trans.*, 1828,) ascribes it to the chemical union of air with the water holding the salt in solution. In other cases, agitation, or the dropping in of a crystal or other solid, produces the same effect. Such phenomena have been shown by Dr. Ure to be affected by electrical changes: he found that, in the voltaic circuit, crystallization always began at the negative pole; but as alkali is there elicited, it may have tended to accelerate the process; or the acid evolved at the positive pole may have retarded it. (*Quarterly Journal*, vol. x., p. 6.)

The presence of *light* also influences the process of crystallization. Thus we see the crystals collected in camphor-bottles in druggists' windows always most copious upon the surface exposed to light; and if we place a solution of nitre in a room which has the light admitted only through a small hole in the window shutter, crystals will form most abundantly upon the side of the basin exposed to the aperture through which the light enters, and often the whole mass of crystals will turn towards it. On looking over the preparations upon the shelves of the laboratory, we frequently meet with analogous cases of crops of crystals formed upon the sides of the bottles facing the windows.

Many saline solutions form arborescent crystalline pellicles, when left to spontaneous evaporation, which slowly travel up the sides of the basin, and gradually proceed down upon the outside; this process also often begins on the side nearest the light, and is sometimes confined to it. Acetate of lime exhibits this appearance in a very beautiful manner. (AIKIN'S *Dict.*, Art. LIGHT.) It is often the result of the capillary attraction of the crystals formed upon the edge of the solution.

The forms of crystals are frequently modified in a remarkable manner by the *medium* from which they are deposited, independent of any chemical change: thus in foul and muddy liquids the crystals are usually deposited in their simplest forms; in gelatinous and saccharine solutions crystals are generally single, and remarkably sharp and regular. Common salt deposited from an aqueous solution containing urea, crystallizes in octoëdra instead of cubes, which are its usual figure; and sal ammoniac under the same circumstances forms cubes, whereas in pure water its crystals are octoëdral. Berzelius says, that very large crystals of nitre may be obtained from its solution in boiling lime-water, which has no analogous effect upon other salts.

Some substances remarkably interfere with the appearance and forms of crystals, although contained in them in very minute quantities; this is especially the case with some of the *hydrocarbons*. If 1 part of the liquid obtained by the compression of oil-gas, and which always exists as vapour in it, be mixed with 8 or 10 parts of strong oil of vitriol, a dark liquor is produced; from this, when diluted with water, filtered, and converted by the addition of carbonate of potash into a sulphate of potash, a salt is obtained, which, upon crystallization, is nacreous, in the form of scales, and has nothing in its appearance common to sulphate of potash: it is however that salt; and is thus affected by the presence of a substance which sometimes does not amount to a two-hundredth part of the salt. The same substance has a still greater power over the sulphate of copper, and in increased quantities (still comparatively small), influences the appearances of other saline bodies.

Independent of the beautiful application of the process of crystallization in refined chemistry to determine the *nature* of bodies by the careful inspection of their forms, the manufacturer avails himself of it to cleanse, purify, and prepare a number of substances useful in the arts, the purity of which is often judged of by the regularity and perfection of their crystalline figures. Common salt is thus obtained by the evaporation of sea-water, and of brine-springs, in consequence of its tendency to crystallize in hot liquors, which retain the other salts that are present in

more permanent solution. Epsom salt, or sulphate of magnesia, is freed by crystallization, from the chloride of magnesium with which it is mixed in the residue of sea-water, after its common salt has been taken out: the magnesian chloride is very difficultly crystallizable, and remains in what is called the *mother liquor*, or residuary solution, which on account of its excessive bitter taste, is known in our salt-works by the name of *bittern*. Nitre is refined, by the facility of its crystallization, for the manufacture of gunpowder, and so cleansed of common salt and other impurities with which it is usually contaminated in the state in which it is imported from India. Numerous other instances of the application of the process of crystallization to the purposes of the arts and manufactures will appear in the sequel.

§ 2.—THEORIES OF CRYSTALLIZATION.

WE may now proceed to notice the *structure* of crystallized bodies, upon which the *Theories of Crystallization* are founded.

It has already been observed, that crystallized bodies, natural and artificial, affect one form in preference to others. The fluor-spar of Derbyshire crystallizes in cubes; so does common salt. Nitre assumes the form of a six-sided prism, and sulphate of magnesia that of a four-sided prism. But these forms, especially as respects natural crystals, are liable to various modifications. Fluor-spar sometimes crystallizes in the form of octoëdra; and there are so many forms of carbonate of lime that it is difficult to select that which most commonly occurs. Romé de L'isle referred these variations of form to certain truncations of an invariable primitive nucleus; and Gahn afterwards observed, that when a piece of calcareous spar was carefully broken, all its particles were of a rhomboidal figure. This induced Bergman to suspect the existence of a primitive nucleus in all crystallized bodies (*Physical and Chemical Essays*, vol. ii., p. 1). When Haiüy entered this field of inquiry, he not only corroborated the opinions of Bergman, and submitted former hypotheses to experimental proof, but traced with much success the laws of crystallization, and pointed out the modes of transition from primary to secondary figures. (*Traité de Minéralogie*, Paris, 1801.) Since the time of Haiüy the study of crystallization, especially in its relations to mineralogy, has been pursued and extended by G. Rose, (*Elements of Crystallography*,) by Professor Whewell, (*Philosophical Transactions*, 1825,) by M. Mohs, and by Professor Weiss, of Berlin; the latter is the founder of a new system of crystallography, having reference to the geometrical relations of their exterior forms rather than to their ultimate molecules or internal structure.

Those who are in the habit of cutting and polishing certain gems, have long known that they only afford smooth surfaces when broken in one direction; and that in others the fracture is irregular and uneven. This is the case with crystallized bodies in general. If we attempt to split a cube of fluor-spar with the blade of a knife, assisted by a hammer, we shall find that it will only yield kindly in the direction of the solid angles; and pursuing the division in these directions, an octoëdron will be the resulting figure, as in fig. 13. The new planes resulting from this *cleavage* of the crystal, are called its *cleavage-planes*. The line

produced by the meeting of two planes is the *edge* of the crystal: and the meeting of any two lines or edges, forms a *plane angle*. A *solid angle* is produced by the meeting of three or more plane angles. In the annexed diagram, $abcd$ are the exterior planes of the crystal; ee its edges; ff its solid angles. (For further details respecting these terms, see Mr. BROOKE'S *Familiar Introduction to Crystallography*.)

In splitting a six-sided crystal of calcareous spar, we find that of the six edges of the superior base three alternate edges only will yield to the blow: those, for instance, marked a, b, c , (fig. 14); and the division will take place in a plane inclined at an angle of 45° . The three intermediate edges resist this division. But in dissecting the inferior base of the crystal, the intermediate edges will alone yield, namely, a, b, c . If we continue this dissection in the same directions, we shall at length obtain the obtuse rhomboid, which is seen in this diagram in its relative situation to the including prism.

We thus then arrive at the *primitive form* of the calcareous spar; and from whatever secondary form it has been obtained, it is always a *rhomboid*, having obtuse angles of $105^\circ 5'$. But an obtuse rhomboid is also the primitive form of other bodies, as of pearl-spar, iron-spar, and tourmalin. But here the inclination of the surface points out a difference. Thus the primitive angle of pearl-spar is $106^\circ 5'$, of iron-spar 107° , (Wollaston, *Phil. Trans.*, 1812,) and of tourmalin $113^\circ 10'$. The temperature, however, at which these measurements are taken, should be noted, for it appears to affect the mutual inclinations of the planes of crystals. In the case of carbonate of lime, it amounts, according to Mitscherlich (*Ann. de Ch. et Ph.*, xxv. 108), to as much as $8\frac{1}{5}$, in the interval of temperature between 32° and 212° . As

the temperature augments, the obtuse dihedral angles diminish; that is, the smaller axis of the rhomboid dilates more than its other diagonals, so as to cause an approach to the cubical form. When melted litharge is allowed slowly to solidify and cool, when it reaches a particular temperature it splits into small fragments: if a little of the double sulphate of potassa and copper be fused over a spirit lamp, it congeals into a brilliant green solid; but as its temperature falls to about 212° , it suddenly is resolved into a heap of incoherent powder. These phenomena are referred by Mr. Daniell to the inequality of their respective contractions.

The instruments which are used for measuring the angles of crystals are termed *goniometers*. The simplest of these (fig. 15) consists of a protractor, or semicircular scale of degrees, AA , and a small pair of compasses or nippers, BBB , destined to receive the crystal.

The centre of the pair of compasses is made moveable, like those of the common proportional compasses, so as to permit the legs BB, and BCB to be considerably lengthened or shortened, when the two pieces are applied to each other. The fixed leg, BB, is represented as beneath the moveable one BCB, or radius measuring 90° , and the lower end of the centre-pin, which could not be shown in

the wood-cut, is made to fit the hole or centre in the protractor precisely at the same time that a stud or projecting piece of brass, being admitted into the long perforation *a* of the leg BB, the piece becomes steadily attached to the protractor or semicircle, as is seen in the figure.

The application of this instrument is obvious. The crystal to be measured is applied between the compasses, which, being thus set, are applied to the protractor, and the value of the angle may be read off at the fiducial edge of the leg BCB. It is, however, seldom that accurate results can thus be attained, for the surfaces of crystals are generally too small or too imperfect, to admit of such method of measurement.

The *reflective goniometer* (fig. 16), invented by Dr. Wollaston (*Phil. Trans.* 1809), is a more useful and perfect instrument. It enables us to determine the angles even of minute crystals with great accuracy; a ray of light reflected from the surface of the crystal being employed as radius, instead of the surface itself. Mr. W. Phillips has given the following description and practical details for the use of this instrument, in his *Introduction to Mineralogy*.

a b is the principal circle, graduated on one edge to half degrees, and divided, for convenience into two parts of 180° each; (it is graduated only in part in

the annexed sketch). c is a brass plate, screwed upon, and supported by, the pillar d , and graduated as a vernier. ff is the axle of the circle ab , and passes through the upper part of the two pillars de , the other ends of which are inserted into a wooden base m . gh is an axle, enclosed within ff , and turned by means of the smallest circle i , which communicates a motion to all the apparatus on the left of h , without moving the principal circle ab . k is a circle, to which is attached the axle of the principal circle. If therefore we would move the latter, it will be done by moving k , and as the axle of the principle circle includes that of the apparatus on the left of h , we must necessarily give a motion to the whole instrument by moving the circle k .

These two movements being understood, let us now suppose that we want to measure a crystal; a rhomboid of carbonate of lime, for instance*. Let l be the rhomboid, attached by means of wax to one end of a plate of brass n ; the other end of the plate being placed in a slit in the upper part of the circular brass stem o , which passes through the tube p , to which it is so adjusted as to allow of being moved either up or down, or circularly, by means of the circle q . The tube p is fixed to the curved brass plate r , which is attached, but so as to allow of motion, to another curved plate s , by means of a pin t , the other end of the latter plate being connected with the concealed axle gh , to which a motion is given by turning the little circle i . By means of the pin t and the tube p , therefore, we have two motions, in addition to the two before described as belonging to the axles of the instrument. The inner axle, however, may be said to be the centre of all the motions. It will, therefore, be of advantage that the rhomboid of carbonate of lime should be placed as nearly on a line with that axle as possible: this will be sufficiently adjusted by means of the stem o , which admits of being raised or depressed at pleasure.

The use of this instrument depends on the reflecting power of the polish on the natural planes, or fractured surfaces of minerals: and that this is in some cases very powerful, any one may convince himself by looking upon a very brilliant plane, held beneath the eye, with its edge nearly touching the lower lid, and not far distant from a window; he will then observe the reflection of the bars very distinctly. Let us then suppose the goniometer, as above represented, to be distant from a window from eight to twenty feet. Let, then, v be a *black line* (the use of this is essential) drawn on the wainscot between the window and the floor, and *perfectly parallel* with the horizontal bars of the window. If, then, the eye be placed almost close to the rhomboid l , a reflection of one of the bars will be seen on one of its planes. Let us suppose the reflection to be in the direction of the lower dotted line on the plane; and it will be clear that it cannot be parallel with the bar of the window, not being even with the black line v . It must therefore be adjusted.

* As it is necessary that this instrument when used should be perfectly steady, it should be placed upon a firm table, and may be raised to a convenient level (about a foot above it), by its

pyramidal case, the top of which is represented in the wood-cut; m is the base of the goniometer, and $y y$, two hollowed slips of wood which receive it.

This may, perhaps, be done by slightly drawing to the left the circle g , which communicates motion by means of the pin t ; or perhaps it may be done by giving a circular motion to the stem o . By one of these two motions, or by both, it may certainly be effected. If, however, the reflection appears to be like the upper dotted line, that is, parallel with the black line, v , we must first convince ourselves that it is so, simply by depressing the crystal a little by means of moving the little circle i , so as to bring the reflection *upon the black line*. This being adjusted, which must be done precisely, we then turn the crystal, by turning the little circle i , until the reflection of the *same bar* be seen on the next plane, perfectly *on a line with and upon the black line v* . However, in adjusting the second, we may disturb the first reflection. By perseverance it will be found that both can be adjusted by means of one or other of the movements by the stem o , or the pin t , or by the help of both, and a short experience will do away the chief difficulties. Both reflections being precise, we are now, by means of the circle k , to turn the principal circle until it is arrested by the stop x on the pillar d ; it will then be found that 180 on the principal circle coincides with o on the vernier. In doing this, however, we may slightly disarrange the reflections on the plane of the crystal, which may be re-adjusted simply by moving the little circle i , which will not disturb the principal circle $a b$: we must be certain, however, *that 180 on it forms a line with o on the vernier, at the same time that the reflection of the bar is seen along the black line*. One movement more, and the measurement will have been made. Turn the circle k , keeping the eye almost close to the rhomboid, until the reflection of the *same bar* is seen on the adjoining plane *precisely upon the black line v* , and the operation is completed. It must then be observed what proportion of the principal circle has been moved. Suppose that 105 on it be now on a line with o on the vernier;—it is the value of the angle. But suppose it to be a little more than 105 and less than $105\frac{1}{2}$: it must then be observed *which line of the vernier touches, or forms but one line with*, another line on the principal circle: suppose it to be 5 on the vernier, the angle is then $105^{\circ} 5'$, which is the true value of the obtuse angle of a rhomboid of carbonate of lime.

In following the method of dissection above described, Haüy obtained six *primitive forms*, which by further mechanical division, may be reduced to three *integral elements*. The primitive forms are:—

1. The cube parallel-opipedon, &c. (Fig. 17.)
2. The tetraëdron. (Fig. 18.)
3. The octoëdron. (Fig. 19.)

4. The hexangular prism. (Fig. 20.)

5. The rhombic dodecaëdron. (Fig. 21.)

6. The dodecaëdron with isosceles triangular faces. (Fig. 22.)

The integral elements are:—

1. The parallelopiped, or simplest solid, having six surfaces parallel two and two. (Fig. 17.)

2. The triangular, or simplest prism, bounded by five surfaces. (Fig. 23.)

3. The tetraëdron, or simplest pyramid, bounded by four surfaces. (Fig. 18.)

The *secondary* forms are supposed to arise from *decrements* of particles taking place on different edges and angles of the primitive forms. Thus a cube, having a series of decreasing layers of cubic particles upon each of its six faces, will become a dodecaëdron, if the decrement be upon the edges (fig. 24); but an octoëdron, if upon the angles; and by irregular, intermediate, and mixed

decrements, (fig. 25), an infinite variety of secondary forms would ensue, as the annexed figures show. It thus appears then, that every crystal may be supposed to include an invariable nucleus, or *primary* form, from which the *secondary* forms are derived, by certain *laws* of *decrement*.

The above illustrations have been taken from Haiiy as furnishing the simplest instances of these theoretical views, but other crystallographers have given very different statements of the number and nature of the primary

forms. Mr. Brooke (*Introduction*, p. 6) has enumerated fifteen, namely, 1. The *cube*, contained within six square planes (fig. 17). 2. The *regular tetraëdron*, contained within four equilateral triangular planes (fig. 18). 3. The *regular octoëdron*, resembling two four-sided pyramids united base to base; the planes are equilateral triangles, and the common base of the two pyramids (or the *base* of the *octoëdron*) is a square (fig. 19).

4. The *rhombic dodecaëdron* contained between twelve equal rhombic planes (fig. 21).

5. The *octoedron with a square base* (fig. 26), contained within eight equal isosceles triangular planes; the square base distinguishes it from figures 27 and 28, and is the only part of the figure which is constant.

6. The *octoëdron with a rectangular base*, its planes are generally isosceles triangles, but not equal (fig. 27).

7. The *octoëdron with a rhombic base*, contained

within eight equal *scalene* triangular planes: all its dimensions are variable (fig. 28). 8. The *right square prism* (fig. 29). (A prism is a solid whose lateral edges are parallel, and whose terminal planes are also parallel: those which stand perpendicularly when resting on their base, are called *right* prisms; those which incline, are called *oblique* prisms.)

9. The *right rectangular prism* (fig. 30), whose three edges, a b c , are unequal; for if any two of those were equal, the prism would be square.

10. The *right rhombic prism* (fig. 31), differing from the preceding in the planes a a being rhombs. 11. The *right rhomboidal prism* (fig. 32), in which the planes a a are rhomboids. 12. The *oblique rhombic prism* (fig. 33). 13. The *oblique rhomboidal prism* or *doubly oblique prism* (fig. 34). 14. The *rhomboid*, or *rhomboëdron*, bounded by six equal rhombic planes (fig. 35). 15. The *regular hexagonal prism* (fig. 36). In reference to the geometrical relations of these forms to each other, and to the production of secondary forms, I must again refer to Mr. Brooke's *Introduction*.

The geometrical forms of crystals have been referred by Weiss to certain lines, in respect to which each face is accompanied by others having the same positions and properties, and which are termed *axes of symmetry*. A rhomboid of calc-spar, for instance, may be so placed with one

of its obtuse angles uppermost, as that the three faces which meet there shall be equally inclined to the perpendicular line. "In this position every derivative face which is obtained by any modification of the faces or edges of the rhomboëdron, implies either three or six such derivative faces; for no one of the three upper faces of the rhomboëdron has any character or property different from the other two; and therefore there is no reason for the existence of a derivative from one of the primitive faces which does not equally hold for the others. Hence the derivative forms will in all cases contain none but faces connected by this kind of correspondence; the axis thus made vertical will be an axis of symmetry, and the crystal will consist of three divisions ranged round this axis and exactly resembling each other. But this is only one of the kinds of symmetry which crystalline forms may assume: instead of being *uniaval*, they may have three axes of complete equal symmetry at right angles to each other, as the cube and regular octoëdron; or two axes of equal symmetry perpendicular to each other, and to a third axis which is not affected with the same symmetry with which they are; such a figure is a square pyramid: or they may have three rectangular axes all of unequal symmetry, the modifications referring to each axis separately from the other two. These systems are respectively distinguished in the nomenclature of Mohs as the *rhomboëdral*, the *tessular*, the *pyramidal*, and the *prismatic*." (DANIELL'S *Introd.* § 124. See also in reference to Weiss's system, TURNER'S *Elements of Chemistry*, 6th edit.)

In examining the forms and texture of crystals, we occasionally

37

meet with cases to which the theories of primary and secondary forms are not satisfactorily applicable. A slice of fluor-spar, for instance, obtained by making two successive and parallel sections, may be divided into acute rhomboids; but these are not the primitive form of the spar, because, by the removal of a tetraëdron from each extremity of the rhomboid, an octoëdron is obtained (fig. 37). Thus, as the whole mass of fluor may be divided into tetraëdra and octoëdra, it becomes a question which of these forms is to be called primitive, especially as neither of them

can fill space without leaving vacuities, nor can they produce any arrangement sufficiently stable to form the basis of a permanent crystal. Mr. Daniell, in the following figures, has represented

38

Tetraëdral Tetraëdron.

39

Octoëdral Tetraëdron.

Octoëdral Octoëdron.

Tetraëdral Octoëdron.

these constructions of the tetraëdron and octoëdron each with tetraëdral and octoëdral particles, in which it is seen that the tetraëdral structure is interspersed with octoëdral vacuities, and the octoëdral with tetraëdral spaces; so that one might be conceived to be taken out of the other.

"All bodies," he observes, "may be considered as attracting each other, as if the whole of their matter were condensed into their centres of gravity, which therefore would in all cases be drawn as closely as possible together: under this law solid tetraëdra and octoëdra would apply themselves to each other by their sides, and not by their edges."

To obviate such incongruities, Dr. Wollaston (*Phil. Trans.*, 1813,) following out an hypothesis previously developed to a considerable extent by Dr. Hooke, proposed to consider the primitive particles as *spheres*, which, by mutual attraction, have assumed that arrangement which brings them as near as possible to each other. When a number of similar balls are pressed together in the same plane, they form equilateral triangles with each other (fig. 42); and if balls so placed were cemented together and afterwards broken asunder, the straight lines in which they would be disposed to separate would form angles of 60° with each other. A single ball, placed anywhere on this stratum, would touch three of the lower balls, and the planes touching their surfaces would then include a regular tetraëdron (fig. 43). A square of four balls, with a single ball

resting upon the centre of each surface would form an octoëdron (fig. 44); and upon applying two other balls at opposite sides of this octoëdron, the group will represent the acute rhomboëdron (fig. 45); or by placing a ball on each face of the octoëdron, it becomes a cube (fig. 46).

Thus the difficulty of the primitive form of fluor, above alluded to, is done away, by assuming a sphere as the ultimate molecule. By oblate and oblong spheroids other forms may be obtained. Thus by

47

oblate spheroids having their axes in the proportion of 1 to 2·87, an oblate rhomboëdron, the angles of which would correspond with those of calc-spar, would result, and all such solids would split in directions parallel to their faces (fig. 47). With *oblong* spheroids, on the contrary, (fig. 48), the centres would approach nearest to each other by mutual attraction when

48

their axes were parallel and their shortest diameters in the same plane; whence a solid which would split into plates at right angles to its axis, and the plates would be divisible into equiangular three or six-sided prisms; a cleavage belonging to phosphate of lime, to the beryl, and other minerals.

49

50

Mr. Daniell (*Quarterly Journal of Science and the Arts*, vol. i., and *Journal of the Royal Institution*, vol. ii.) has offered some curious and important confirmations of Dr. Wollaston's hypothesis. If an amorphous piece of alum be immersed in water, and left quietly to dissolve, it is unequally acted upon by the fluid (see fig. 1): and the mass presents the forms of octoëdra, and sections of octoëdra, as it were carved or stamped upon its surface, as in the annexed figures, 49 and 50. This appearance is produced when the attraction of the water for the solid is nearly counterbalanced by its mechanical texture. The crystals formed by this species of dissection are highly curious, from their modifications and relative positions,

as the same group presents the primitive form, as well as its truncations and decrements.

Other salts yield other figures, and by more complicated chemical action, as of acids upon carbonate of lime, the metals, &c., analogous results are obtained. Here, then, instead of dividing a crystal by mechanical force, its structure is gradually developed by the process of solution. In these cases two circumstances are particularly remarkable; the crystals are different; and their forms vary with the different faces of the original mass. In one direction we observe octoëdra and sections of octoëdra; in another, parallelograms, modified by certain determinate intersections. If, in either of these positions, we turn the mass upon its axis, the same figures

are perceived at every quadrant of a circle; and if we suppose the planes continued, they will mutually intersect each other, and various geometrical solids will be constructed. In this way, alum alone furnishes octoëdrons, tetraëdrons, cubes, four and eight sided prisms, either with plain or pyramidal terminations, and rhombic parallelopipedons. It is evident, then, that no theory of crystallization can be admitted, which is not founded upon such a disposition of constituent particles, as may furnish all these modifications, by mere abstraction of certain individuals from the congeries, without altering the original relative position of those which remain; and these conditions may be fulfilled by such an arrangement of spherical particles, as would arise from the combination of an indefinite number of balls endued with mutual attraction; and no other geometrical solid is adequate to the purpose; and where bodies afford crystals differing from the octoëdral series, an analogous explanation is furnished by supposing their constituent particles to consist of oblate spheroids whose axes bear different proportions to each other in different substances. Hence we may also conclude, that the internal structure of all crystals of the same body is alike, however the external shapes differ. In corroboration of the above hypothesis, Mr. Daniell remarks that the hexaëdron is, of all geometrical figures, that which includes the greatest capacity under the least surface. "If, therefore, the ultimate particles of crystalline bodies be spheres or spheroids, the greatest possible number in the least space will be included in this form. It is probable that the exterior shape of every crystal is determined by the nucleus first formed by a certain definite number of particles, which, by the power of mutual attraction, overcome the resistance of the medium in which they were suspended, or from which they were separated. This number may vary with the solvent, or other contingent circumstances. Four spherical particles, thus united, would balance each other in a tetraëdral group, six in an octoëdral group, and each would present particular points of attraction to which all subsequent deposits would be directed. Now, let us imagine two nuclei formed in the same solution, whose axes run in contrary directions; their increase will consequently be in contrary directions, and each will attract a particular system of particles from the surrounding medium. If these two systems should cross each other in their course, a greater number will be brought within the sphere of mutual re-action at the point of junction, and they ought to arrange themselves in the least possible compass. The facts here answer to the theory. If we select any crystals, having others crossing them nearly at right angles, and separate them, the points of junction invariably present an hexaëdral arrangement."

We have already adverted to the important applications of the phenomena and process of crystallization to theoretical and practical chemistry. To the mineralogist, the science of crystallography is equally indispensable; it enables him to determine the species to which minerals belong, and to recognise their varieties by their external and mechanical characters.

Under the term *isomorphism* we have above alluded to the close approximation, if not identity, of form, which certain crystallized compounds of analogous atomic constitution assume. Of these isomorphous

bodies a table has been drawn up by Professor Johnston (*Report on Chemistry to the British Association*). The following are their principal groups, (TURNER'S *Elements*, 6th edit., p. 646,) their atomic analogies will be afterwards noticed.

1.	Silver.	8.	Salts of soda.
	Gold.		— oxide of silver.
2.	Arsenious acid.	9.	Salts of baryta.
	Sesquioxide of antimony.		— strontia.
3.	Alumina.		— lime (in aragonite.)
	Peroxide of iron.		— oxide of lead.
4.	Arseniates.	10.	Salts of lime.
	Phosphates.		— magnesia.
5.	Sulphates.		— protoxide of iron.
	Seleniates.		— manganese.
	Chromates.		— zinc.
	Manganates.		— nickel.
6.	Perchlorates.		— copper.
	Permanganates.	11.	Salts of alumina.
7.	Salts of potassa.		— peroxide of iron.
	Salts of ammonia, with 1 atom of water.		— oxide of chromium.
			— sesquioxide of manganese.

Dr. Turner observes that there are other analogies among isomorphous bodies independent of form: arsenic and phosphorus for instance resemble each other in odour, in forming gaseous compounds with hydrogen, in the relative proportions of oxygen with which they combine, and in the quantity of water in their salts. Selenium and sulphur resemble each other in fusibility, volatility, and combustibility, and in forming analogous atomic compounds with hydrogen and with oxygen: sulphuric acid and selenic acid, and their respective salts, are equally allied. Baryta and strontia, lime and magnesia, cobalt and nickel, exhibit similar relationships. Isomorphous substances also readily crystallize together, and are difficultly separated. Dr. Daubeny, for instance, found that a weak solution of lime in water is very sluggishly affected by the delicate test of oxalate of ammonia, when much sulphate of magnesia is at the same time present; and Dr. Turner found that chloride of magnesium could not be purified from lime by oxalate of ammonia. From a mixed solution of the protosulphates of copper and iron, crystals, retaining the same quantity of water, and having the same form as those of protosulphate of iron, are obtained, though they include a large quantity of copper. The protosulphates of zinc and copper, of copper and magnesia, of copper and nickel, zinc and manganese, manganese and magnesia, crystallize together, having the same form and the same quantity of water as the protosulphate of iron. These salts are not separable by repeated crystallizations, and yet they are not chemically united in definite proportions as true double salts, but merely crystallize together. In minerals similar isomorphous mixtures occur: thus the garnet is a double silicate of alumina

and lime, in which, as also in alum, the alumina may be replaced by peroxide of iron; or they may be both present in any proportion, provided their sum be equivalent to either singly. So also while peroxide of iron replaces the alumina, the lime might be replaced by protoxide of iron, and a mineral would result, having the form of the garnet, but containing neither alumina nor lime, and being in fact a compound of the silicate of peroxide of iron with the silicate of protoxide of iron, instead of, as in the garnet, silicate of alumina with silicate of lime. Other substitutions of isomorphous elements or compounds might take place without influencing the crystallographic character; and from other mineral compounds similar instances might be selected.

Another curious fact in regard to crystals, also noticed by Mitscherlich, is the assumption by the same substance of two incompatible crystalline forms: such bodies are therefore called *Dimorphous*. This is the case with sulphur, which when crystallized by fusion yields oblique rhombic prisms, but is deposited from certain of its solutions in rhombic octoëdrons. Pure carbon, in the form of diamond, crystallizes in octoëdrons, but as graphite, in hexagonal plates. Carbonate of lime in calc-spar has the rhomboëdral structure, but in arragonite that of the rectangular octoëdron; and there are other analogous cases. It has been found in regard to these cases of dimorphism that each form has its peculiar density; the specific gravity of calc-spar for instance being 2.71; that of arragonite is 2.94. The temperature too at which the crystals are formed is another influencing cause: thus when carbonate of lime is precipitated by adding chloride of calcium to carbonate of ammonia, the grains of the powder are rhomboëdral if thrown down at the temperature of 50° , but octoëdral, if at 150° . (G. ROSE, *Phil. Mag.*, xii., 465.)

There are, moreover, some cases in which solids themselves change their molecular arrangement: thus sugar which has been boiled down to such a consistency as to solidify on cooling, forms a transparent vitreous mass, as seen in what is termed *barley-sugar*; but this, if kept for some time, becomes opaque, granular, and friable. Old brass wire is apt to grow brittle. Prismatic crystals of sulphate of nickel and of seleniate of zinc, when exposed to the sun, become opaque, and break up into small octoëdrons. Crystals of sulphate of magnesia or of sulphate of zinc, heated in oil to a temperature of about 126° , become opaque, and when broken are found to consist of a number of individual crystals, easily separated. (MITSCHERLICH. See also METHUON, *Quart. Journ.* i., p. 123, and GREGORY WATT's experiments on the effect of slow cooling upon certain substances, *Phil. Trans.* 1804, p. 279.) Dr. Macculloch has noticed the crystalline texture occasionally acquired by some kinds of sandstone, which, having served for the hearths of furnaces, have been long exposed to heat, though always far below their point of fusion. But no modification of form is more remarkable than that of *glass*, a state, of which many bodies are susceptible, and characterized by a curved or conchoidal (*glassy*) fracture; it never breaks with plane surfaces or *sparry*. Under certain circumstances, however, vitreous compounds pass into crystalline forms, and in large masses of glassy slag, globular nodules of radiating and acicular crystals are not very uncommon. Arsenious acid presents a similar phenomenon: when recently fused or sublimed it is usually

glassy and transparent, but it gradually becomes an opaque, white, crystalline solid; the change commencing at the surface, and gradually proceeding to the centre. This change from the vitreous to the crystalline state sometimes takes place suddenly, and gives rise to a curious phenomenon observed by G. Rose: the vitreous acid, when dissolved in hot and dilute hydrochloric acid, deposits crystals of the opaque acid, and a flash of light is emitted at the formation of each crystal; this appearance is not observed when the hydrochloric solution is made with the opaque or crystalline, instead of the transparent or glassy, acid.

There are other cases in which what may be termed dimorphism is to a certain extent produced by changes of temperature. Thus the red sulphuret and the red oxide of mercury both become black when highly heated, but reassume their red colour on cooling; periodide of mercury is often yellow whilst hot, but becomes scarlet as it cools. Oxide of zinc is yellow whilst hot, and white when cold. Even gaseous bodies are susceptible of changes of this kind, of which nitrous acid vapour furnishes an instance, being nearly colourless when very cold, but of a deep orange when heated. When precipitated sulphuret of antimony is dried at about 400° it retains its deep orange colour, but when heated a little higher, it shrinks, blackens, and acquires a metallic lustre, without further loss of weight; and on the other hand, the black sulphuret, when strongly heated, and suddenly cooled by throwing it into water, acquires a brown colour.

Certain metallic oxides, such as alumina, peroxide of tin, and oxide of chromium, become insoluble in acids after having been heated to redness; and some of them, in passing from the soluble to the insoluble state, suddenly become luminous, and rise greatly in temperature: this is remarkably the case with gadolinite, which glows when heated, and changes colour, but sustains no change of weight.

The cause of many of these extraordinary phenomena, in which bodies undergo changes in form and properties, whilst their composition is not apparently altered, may in some instances no doubt be referred to modifications of their molecular arrangements; in other cases the loss or evolution of heat is apparent. "The circumstance," says Professor Graham (*Elements of Chemistry*, part ii.), "most certain respecting this change in bodies is that they do not contain a quantity of heat after the change, which they must have possessed before its occurrence, in a combined or latent form. No ponderable constituent is lost, but there is this loss of heat. A change of the arrangement of the particles, it is true, might occur at the same time in some of these bodies, such as is observed when sulphite of soda is converted by heat into a mixture of sulphate of soda and sulphuret of sodium, without change of weight; but it would be difficult to apply an explanation of this nature to oxides, such as alumina and peroxide of tin, which contain only two constituents. The loss of heat observed will afford all the explanation necessary, if heat be admitted as a constituent of bodies equally essential as their ponderable elements. As the oxide of chromium possesses more combined heat when in the soluble than in the insoluble state, the first may be justly viewed as the higher *caloruret*, and the body in question may have different proportions of this as well as of any other constituent."

CHAPTER II.

HEAT, LIGHT, AND RADIANT MATTER.

HEAT—ITS EFFECTS AND SOURCES.

HEAT may be considered as the antagonist power to attraction*, one of its most obvious effects being the dilatation or expansion of bodies; so that, whenever a body is heated, it is enlarged in bulk, and consequently diminished in specific gravity. These changes are temporary only; for, on cooling, the body regains its former dimensions, and a further reduction of heat causes a proportionate diminution of bulk: hence, bodies are said to *expand when heated*, and to *contract when cooled*; a law to which the exceptions are very limited.

We know nothing of the *cause* of heat, but we generally refer the effects perceived to the presence of a highly attenuated and imponderable fluid, the particles of which repel each other, but are attracted by all other substances: it is supposed to pervade all matter, and to be diffused over the whole universe. To this supposed subtle fluid the French nomenclaturists gave the name of *caloric*—a term which has been much employed, under the idea that the word *heat*, which is applied both to cause and effect, might lead to ambiguity: this, however, it need not; and whatever may be the cause of the phenomena, *the word heat may be used to denote that state or condition of a body which excites in us the sensation of heat.*

§ 1.—EXPANSION IN GENERAL.

BODIES exist in nature under three forms,—*solids, liquids, and gases or vapours*; these three forms of matter suffer expansion and contraction in very different degrees, when exposed to similar changes of temperature: in solids, the change of dimensions is comparatively small, and refined means are necessary to determine and measure it; in liquids it is more obvious; and in gases extremely apparent.

To show the *expansion of a solid*, a bar of metal for instance, we may be provided with a gauge which measures its length and breadth at ordinary temperatures; and it will be found that, when heated, it will no longer pass through the apertures which readily admitted it when cold. *a* (fig. 51) is a brass bar with a handle attached, the length of which, at common temperatures, is exactly equal to the notch *c* in the plate *b*, and it exactly passes into the circular aperture *d*. If the bar be now heated by plunging it into boiling water, it will be found so much enlarged in all its dimensions, as not to pass through the apertures. If, on the contrary, it be cooled by ice, it will then contract, and pass them more readily.

* Fresnel observes that a sensible repulsive power is conferred by heat upon bodies delicately suspended in vacuo.—(*Ann. de Ch. et Ph.*, xxix., 57 and 107.)

The expansion and contraction of a *liquid*, when heated, are easily shown as follows: pour into a large thermometer tube (fig. 52) a quantity of brandy, so as to fill the bulb, and rise in the stem up to the mark *a*. Plunge it into warm water, and the spirit will dilate and rise in the tube up to the point *b*; remove it, and suffer it to regain its original temperature, and its bulk will return to *a*; but if it now be put into ice, the liquid will contract, falling in the tube to *c*; but again expanding, when removed into the atmosphere at ordinary temperatures.

Aëriform bodies far exceed the former in expansibility. Place a thermometer-tube, with its open end in a glass of water, as in fig. 53, and apply the heat of the hand to the bulb *a*; this will be sufficient to expand the air within, so that bubbles will escape through the water, and on removing the source of heat, the water will mount in the tube, showing, by the place it occupies, the degree of expansion which the air had suffered.

Thus far the general fact of the *expansion of the different forms of matter by heat, and their contraction by cold*, is easily demonstrated; but there are peculiarities belonging to each, and applications resulting from them, which must be entered into more in detail.

§ 2.—OF THE EXPANSION OF SOLIDS.

DIFFERENT solids possess different degrees of expansibility, and among them the *metals* are most susceptible of change of bulk; but each solid possesses a rate of expansion of its own. Lead, for instance, expands in volume one-350th; iron, one-800th; glass, one-1000th; in other words, 350 cubic inches of lead become 351; 800 of iron, 801; and 1000 of glass, 1001. In consequence of the numerous purposes to which glass and the metals are applied, and with which these changes of bulk interfere, it becomes necessary to examine their extent with precision.

The following table shows the linear dilatation of glass and several of the metals between the freezing and the boiling point of water. (DANIELL.)

1000000 of Glass tube . become	1000861	1000000 of Copper . become	1001712
" Crown glass "	1000875	" Brass "	1001783
" Platinum "	1000856	" Silver "	1001890
" Cast iron "	1001111	" Tin "	1001937
" Steel "	1001189	" Lead "	1002867
" Gold "	1001460		

The expansion in volume may be obtained without sensible error by trebling the number which expresses the increase in length, where, as in the above cases, the fraction of its length is small; thus, if a glass tube elongates by one-1248th when heated from 32° to 212° , its cubic space will have increased by three-1248ths; or one-416th of its former capacity.

In the range of temperature between 32° and 212° , these expansions are apparently nearly equable; but the experiments of Dulong and Petit (*Ann. de Chim. et Phys.*, and *Annals of Philosophy*, xiii. 164), prove that the rate of expansion increases with the temperature, as shown in the following tables:—

I. Increasing Dilatation of Glass by Heat.

Temperature by Air Thermometer. (Fahrenheit.)	Mean absolute Dilatation of Glass for each Degree.	Temperature by a Thermometer made of Glass.
From 32° to 212°	$\frac{1}{69660}$	$212^{\circ}0$
„ 32° to 392°	$\frac{1}{65340}$	$415^{\circ}8$
„ 32° to 572°	$\frac{1}{59220}$	$667^{\circ}2$

II. Increasing Dilatation of Metals by Heat.

Temperature by Air Thermometer.	Mean Dilatation of Iron for each Degree.	Temperature by Iron-rod Thermometer.	Mean Dilatation of Copper for each Degree.	Temperature by Copper Thermometer.	Mean Dilatation of Platinum for each Degree.	Temperature by Platinum Thermometer.
212°	$\frac{1}{50760}$	212°	$\frac{1}{34120}$	212°	$\frac{1}{67860}$	212°
572°	$\frac{1}{40678}$	$702^{\circ}5$	$\frac{1}{31860}$	$623^{\circ}8$	$\frac{1}{65340}$	$592^{\circ}9$

“It appears that, at temperatures beyond 212° , glass expands in a greater ratio than mercury, and as the mercurial thermometer measures the *difference* of the expansion of the glass and metal upon the supposition that they are both uniform, its degrees require a correction in the upper part of the scale, when compared with the equal dilatation of air. Thus the temperature of 586° on the mercurial thermometer corresponds with 572° on the air thermometer; while, from the third column of the first table, it appears that the expansion of glass alone, supposed to be equable, would indicate 667° for the same point. The second, fourth, and sixth columns of the second table show the mean expansion for each degree of iron, copper, and platinum when heated from 32° to 212° , compared with that from 32° to 572° ; the third, fifth, and seventh columns indicate the degrees on thermometric bars of these metals, corresponding to the temperature of 572° on an air thermometer.” (DANIELL, § 148.) By the aid of his register pyrometer, Mr. Daniell has constructed the following table, showing the progressive amount of the expansion of several metals, up to their point of fusion.

Progressive Dilatation of Solids.

1000000 PARTS, AT 62°.

	At 212°.	At 662°.	At Fusing Point.
Black Lead Ware . .	1000244	1000703	
Wedgwood Ware . .	1000735	1002995	
Platinum	1000735	1002995	{ 1009926 maximum, but not fused.
Iron (Wrought) . . .	1000984	1004483	{ 1018378 to the fusing points of cast iron.
Iron (Cast)	1000893	1003943	1016389
Gold	1001025	1004233	
Copper	1001430	1006347	1024376

Tin	1001472		1003798

Dr. Ure has proved, in regard to zinc, that that metal permanently elongates after frequent heating and cooling. "It would seem," he says, "that the plates composing this metal, in sliding over each other, by the expansive force of heat, present such an adhesive friction as to prevent their entire retraction." In regard to the unequal expansion of bodies at different temperatures, the same philosopher remarks, that it is probable every species of matter follows an increasing rate in its enlargement by caloric, for each portion that enters a body must weaken cohesion, and therefore render the operation of the next portion that is introduced more efficacious. The curious fact of the unequal expansion of certain crystals discovered by Mitscherlich has already been mentioned, (p. 118.)

In consequence of the extensive use which is made of iron in the construction of bridges, and as a substitute for timber, mechanics have become more fully aware of the necessity of making due allowance for its expansion and contraction, and such arrangements as may admit of it without injury to the other parts of the building. The arches of the Southwark bridge rise and fall about one inch within the usual range of atmospheric temperatures. Where great lengths of iron pipe are used, as for the conveyance of gas or water, some of the junctions are so contrived as to allow of their elongation and contraction, without fracture. Where iron beams are employed, they must be so placed as to admit of some play without injury to the walls; and where such precaution has not been taken, their contraction and expansion have tended to endanger the building. Iron roofs, in consequence of their situation exposing them to the influence of a hot sun, or to the cold of winter, require peculiar care in this respect; and in other cases, apparently of trivial importance, serious consequences have resulted from the incautious application of iron bars in situations where their changes of bulk could be productive of mischief, as in clamping stones together in the construction of steeples, and in placing iron railings between columns, &c.; for these changes of bulk, small as they are in amount, take place with irresistible force. This fact was well illustrated in an application made of it by M. Molard for restoring the perpendicularity of the walls of the Museum

of Arts and Manufactures in Paris, which, in consequence of the weight of the roof, were bulging outward; he laid iron rods across the building, the ends of which projected through the opposite walls; these rods were then heated, and when in an expanded state a strong iron plate upon either end of each rod was firmly screwed up against the exterior of the wall: during their contraction on cooling the rods drew the walls somewhat nearer together: the bars were then again elongated by heat, the screws being again tightened, and so by a repetition of the process the walls were gradually brought to a perpendicular position. The same process has been applied in the restoration of the cathedral at Armagh.

It appears from the above tables that the expansion of glass and of platinum is nearly similar: hence wires of that metal may be welded into fused glass without inconvenience; but if we substitute a wire of another metal, its different rate of contraction will tend to break the glass as it cools. It is also seen that iron or steel is less expansible than brass; if, therefore, we form a compound bar of these or any other two differently expansible metals, by riveting or soldering them together, such a bar, by changes of temperature, will constantly warp in one direction or other, according to the relative position of the steel and brass. Let fig. 54 represent the compound bar, the steel being uppermost; if we then put it upon a heated plate, the bar will warp, as shown in fig. 55, in consequence of the greater expansion of the brass; if, on the contrary, the compound bar be subjected to cold, it will assume the opposite curve, fig. 56, in consequence of the greater contraction of the brass. A compound plate of silver and platinum is remarkably susceptible of these contortions; and such contrivances have been applied to the construction of instruments for measuring changes of temperature, as in *Breguet's Thermometer*, which consists of a very thin and narrow strip of platinum, plated with silver and coiled into a spiral, one end of which is attached to an upright support, and the other to an index moving over a graduated circle: with changes of temperature the spiral twists and untwists, carrying with it the index: the value of the degrees on the circle is determined by comparison with a mercurial thermometer.

The expansion and contraction of the metals by heat and cold is a serious inconvenience to the chronometer-maker, as necessarily interfering with the rate of going of the clock or watch. The pendulum, to vibrate seconds, must always be of a given length*, and it is obvious that if of metal it will be liable to shorten in winter and lengthen in summer: thus the clock will be fast in the former, and slow in the latter season†.

* The length of the pendulum vibrating seconds in *vacuo* in the latitude of London ($51^{\circ} 31' 8''$ North) at the level of the sea, and at the temperature of 62° , is = 39.13929 inches of Sir George Shuckburgh's standard scale. KATER, *Phil. Trans.*, 1819, p. 415.

† When the bob is let down $\frac{1}{100}$ of

an inch, the clock loses ten seconds in twenty-four hours; hence the elongation of $\frac{1}{1000}$ of an inch will cause it to lose one second per day, and a change of temperature equal to 30° of Fahrenheit will alter its length about $\frac{3}{5000}$ part, and occasion an error in the rate of going, of eight seconds per day.

The contrivances which have been resorted to, to counteract this inconvenience, are numerous, and many of them extremely ingenious;

but any details upon the subject would be misplaced here. The following mode of compensation is, however, particularly illustrated by the principle here explained. *a* represents the pendulum-rod of brass or steel, suspended by the thin plate *b* between the compensation-bars of brass and steel (fig. 54) *c c*, which are firmly fixed at the ends *c*, and are supplied with proper adjustments. Let us now suppose the pendulum exactly vibrating seconds at the temperature of 62° , and that the temperature rises to 80° : in this case, the bar *a* would be elongated, and it would not then vibrate so many as 60 seconds in the minute; but the effect of increase of temperature in the compensation-bars, supposing the brass uppermost, would be to warp them, as in the annexed sketch, fig. 58, and, virtually, to shorten the pendulum; and in cold weather, on the contrary, the rod of the pendulum would be shortened, but the bars warping upwards (as in fig. 59,) would tend to elongate it. A similar plan

of compensation may be applied to the balance-springs of watches, which are affected in the same way, and with the same effects, as the pendulum of a clock.

The dimensions of wood are much less altered by changes of temperature than those of metals; it is, therefore, occasionally used for the rods of very large pendulums; but, in other cases, it is not found effectual, and is liable to be deranged by the varying moisture of the atmosphere.

There are some common operations, in which the expansion and contraction of metals by heat and cold are beneficially applicable: by putting the hoops upon a cask, in a heated state, they gradually contract on cooling, and firmly bind the staves together; and, with the same view, the wheelwright heats the tire of his wheel, that it may firmly press upon the circumference as it cools: so also the plates of large boilers are united by hot rivets, which during their contraction on cooling draw them firmly and securely together.

A very remarkable anomaly as regards the usual laws of expansion and contraction is presented by the fusible alloy of two parts of bismuth, one of lead, and one of tin. A bar of this metal at 32° expands till it attains the temperature of 111° ; it then rapidly contracts by the continued addition of heat up to 156° , when it has attained its maximum density, occupying less space than even at 32° ; it then again progressively

expands, its point of fusion being 201° . (ERMANN.) These extraordinary phenomena are well illustrated by filling a glass test-tube with the fused alloy, and suffering it to cool; this goes on quietly till it arrives at its minimum volume, 156° ; soon after which the tube is suddenly broken by the expansion of the metal during cooling, it attaining its maximum volume at 111° .

§ 3.—EXPANSION OF LIQUIDS.

THE expansibility of different liquids, like that of solids, is liable to variation: ether, for instance, is more expandible than alcohol, and alcohol more so than water, and water than mercury. Liquids are also differently expandible at different temperatures; and, generally speaking, their rate of expansion increases with their temperature. This irregularity is chiefly observed in those liquids which readily boil; where they require a very high temperature to convert them into vapour, it is less observable. The expansion of mercury, for instance, at low and high temperatures, is only slightly dissimilar; hence one of its great advantages in the construction of thermometers. The following Table, by Dr. Thomson, shows the rate of expansion of several liquids between the temperatures of freezing and boiling water.

Temp.	Mercury.	Linseed Oil.	Sulphuric Acid.	Nitric Acid.	Water.	Oil of Turpentine.	Alcohol.
32°	100000	100000	—	—	—	—	100000
40	100081	—	99752	99514	—	—	100539

190	101628	—	103587	—	103617	—	—
200	101730	—	103911	—	—	—	—
212	101835	107250	—	—	104557	—	—

According to Mr. Graham, on being heated from 32° to 212°

Alcohol expands $\frac{1}{6}$, that is 9 measures become 10

Fixed oil . . . $\frac{1}{12}$. . . 12 13

Water . . . $\frac{1}{22 \cdot 76}$. . . 22·76 23·76

Mercury . . . $\frac{1}{55 \cdot 5}$. . . 55·5 56·5

Alcohol, therefore, is six times more expansive by heat than mercury; and in the height of summer spirit of wine will measure about 5 per cent. more than in the depth of winter.

The expansibility of the liquids resulting from the compression of gases is extremely remarkable, for it appears from the experiments of

M. Thilorier (*Ann. de Chim. et Phys.*, LX., 427) that fluid carbonic acid is even more expansible by heat than air; heated from 32° to 86° , twenty volumes of this liquid increase to twenty-nine, which dilatation is about four times greater than that of air. Mr. Kemp has extended this observation to the liquids resulting from the compression of sulphurous acid and of cyanogen, which, though less dilatable than carbonic acid, are much more so than common liquids.

A remarkable correspondence has been observed by Gay Lussac between the rates of expansion of alcohol and sulphuret of carbon, although their boiling points are very different, that of alcohol being 173° , and of sulphuret of carbon 116° : their changes of bulk for changes of temperature are stated to be precisely similar, and they are the only liquids known to possess such a relation.

There is an extraordinary exception to the law of expansion and contraction by heat and cold, in the case of *water*, which, unlike other fluids, *expands when cooled below a certain point**. Other fluids diminish in bulk till they freeze; but if we fill a large thermometer-tube with water, of the temperature, for instance, of 80° , and then plunge the bulb into a freezing mixture, the water goes on shrinking till it has attained the temperature of about 40° ; and then, instead of continuing to contract till it freezes, (as is the case with other liquids,) it slowly expands and rises in the tube until it congeals. In this case the expansion below 40° and above 40° seem to be equal; so that water will be of the same bulk at 32° as at 48 , that is, at 8° degrees above or below 40° . Crichton's experiments place the maximum of density at 42° , (*Ann. of Phil.*, N.S., v., p. 491;) those of Hallström at 39.4 , (*Ann. de Chim. et Phys.*, xxviii., p. 90.) There is an elaborate paper in the *Ann. de Chim. et Phys.* (t. LXX.) by Despretz, upon the maximum density of water and of saline solutions: he places the maximum density of water at $+4^{\circ}$ Centigrade, and states that below the maximum density the dilatation by cold is more considerable than the dilatation by heat above the same point, but that the difference is very minute and may probably be fallacious: that sea water and all saline solutions have a maximum of density: that the maximum of density sinks more rapidly than the point of congelation.

The anomalous expansion of water by cold is productive of some most important consequences in nature; for if water, like other fluids, went on diminishing in bulk, and therefore increasing in density, till it froze, large bodies of water, instead of being only superficially frozen in winter, would become solid masses of ice. Let us take a fresh-water lake as an example. The earth being warmer in winter than the air, the heat is withdrawn from the *surface* of the water by the cold breezes that blow over it, and the whole body of water has its temperature lowered to 40° , *which is the point of its greatest density*, and a temperature congenial to fish and other aquatic animals. The cold now continues to operate upon the surface of the water, but instead of diminishing its bulk, and rendering it *heavier* than the warmer water beneath, it expands and renders it *lighter*; so that, under these circumstances, a stratum of ice-cold water (at 32°) will be found lying upon a mass of warmer water beneath it (at 40°). The influence of the cold continuing, the surface of

* See Prefatory History, p. 44.

the lake will soon freeze, but the water immediately below the superficial coating of ice will be found comparatively warm; and as water is almost a non-conductor of heat, it will be a long time before the ice attains any thickness; and the whole body of water, if of any depth, can never freeze throughout. Indeed, it will be obvious that the retardation of freezing will be proportional to the depth of water which has to be cooled, and hence some very deep basins or lakes are scarcely ever covered with ice.

Perhaps the following experiment may render this property of water more intelligible. Let a a' , fig. 60, represent two cylindrical glass vessels, filled with water at 60° ; b b' are tin trays surrounding and closely fitting the exteriors of the cylinders, and intended to contain a freezing mixture of snow and salt, which in a is applied to the upper *surface*, but in a' to the *bottom* of the water. The first effect of the cold will be to reduce the temperature of the whole bulk of water, in both vessels, to 40° ,

that is, to the point of greatest density. After which it will be found that, in the vessel a , the cooling effect will not proceed downwards, but will be limited to the surface, where the thermometer will gradually fall to 32° , and the water probably freeze; for the ice-cold water being lighter than the water at 40° below,

it will necessarily float upon the surface: a thermometer, therefore, in the upper part of the vessel will fall to 32° , but in the lower part only to 40° . This may be said to represent the case of the lake above described. In the second cylinder a' , the cold, instead of being applied to the surface of the water, is applied to the bottom, and the effect is very different; for now the cooled water becoming lighter, ascends, whilst the warmer water descends, and becoming cooler in its turn, the whole body of water is reduced to the freezing temperature, an effect limited to the *surface* in the other cylinder, which represents what happens in nature, where the cold is always superficial; and ice being lighter than water, it is, of course, formed and remains upon the surface. With respect to sea water, or to a solution of salt in water, it is found that the temperature of the maximum of density becomes lower and lower in proportion to the quantity of salt dissolved.

As liquids, generally speaking, are *enlarged*, and consequently rendered *specifically lighter*, by heat, it follows that, in heating a mass of liquid, very different effects will be produced by applying heat to different parts of the vessel containing it: a and b , fig. 61, represent two tubes of thin glass filled with water. If we apply the flame of the spirit-lamp to the *bottom* of

the tube *a*, the water will soon be heated equally throughout, and boil; and this is the usual way of applying heat, namely, to the bottom of the boiler; but if, as in the tube *b*, we heat the *surface* of the water, we shall find that it may be made to boil in the upper part of the tube, whilst the water at bottom will remain cold. In this case, the water becomes *lighter* by being heated, and consequently floats upon the colder water below, to which scarcely any heat will be communicated.

The currents that ensue, in the ordinary way of heating water, may be rendered obvious by the following experiment:—Fill a cylindrical glass vessel, of the shape annexed, fig. 62, with water, and throw into it a few particles of bruised amber, or any other convenient substance, nearly of the same specific gravity as the water,

so that, if possible, they may neither sink nor float in it; then apply a gentle heat to the centre of the *bottom* of the vessel, and it will be seen that currents immediately begin to ascend in the centre, or axis, and to descend towards the circumference of the vessel, in the direction shown by the darts, or in an inverted direction if the *sides* of the tube are most heated. These currents soon become rapid, and continue till the water boils. It is, therefore, by changes in the specific gravity of the different portions of water, that we succeed in conveying heat throughout the mass. The heated portion becomes enlarged, and, therefore, specifically lighter than the adjacent cold portions through which it ascends; whilst they, descending, come into the contact of the heated surface, and in their turn expand and rise. This goes on till the whole of the water has acquired its boiling temperature, and the currents then cease. Such currents may be established, in properly-constructed vessels, to any extent, and heat thus communicated to water at a considerable distance from the boiler; a system lately adopted very advantageously in heating houses, conservatories, manufactories, and baths. The contrivances for these purposes are very various; but all, of course, imply the necessity of an *ascending* and *descending* current. The annexed (fig. 63) is a form of apparatus employed by Mr. Faraday for the illustration of the direction and extent of these currents, and their application to the conveyance of heat from one place to another. *A* is a large glass flask filled with water, into which the tubes *B C* are tightly fitted by a perforated cork and cement; these tubes are also filled with water, and dip into the flask *D*, which is filled with water deeply tinged blue with indigo; the tube *B* dipping only about half an inch below the surface,

whilst *c* descends nearly to the bottom of the blue liquor, and should be very slightly curved upwards at its extremity. On applying the flame of a spirit lamp, as at *E*, the blue liquid ascends by the tube *B* and circulates through *A*, the water from which descends through *c* into *D*, and thus a circulation of the fluid is kept up and the heat conveyed from one flask to the other.

In Mr. Perkins's apparatus for conveying heat through buildings by the circulation of water, an endless tube is employed, the surface of which is occasionally increased by spiral or other turnings where the heat is to be given off or acquired: the annexed figure (64) may serve to illustrate this principle; it represents a very strong iron tube of about one inch diameter completely filled with water; the spiral *A* passes through a furnace where it is highly heated, and the water is consequently put into motion in the direction of the arrows; the boiling of the water or formation of steam is prevented by the pressure, whence the necessity of the extreme perfection and strength of the tube. *B* represents a second coil which is supposed to be in an apartment where the heat is to be given out. *c* is a screw stopper by which the water may be occasionally replenished. By this form of apparatus the water may be heated to 300° or 400° , or even higher, so as occasionally to singe paper. A larger tube and lower temperature are, however, generally preferable.

§ 4.—EXPANSION OF AERIFORM BODIES AND VAPOURS.

WE may now notice *the effects of heat upon gases, air, and vapours*. These undergo much greater relative changes of bulk than the other forms of matter, but they also present an important peculiarity. In other substances, each individual has its own degree of expansion and contraction, whereas *all pure æriform bodies expand and contract alike*: so that, if we accurately determine the expansion and contraction of any one of them, in a given range of temperature, that knowledge applies to all the rest. It has been ascertained by Dalton and Gay Lussac that 1000 measures of air, when heated from the freezing to the boiling point of water, suffer an increase in bulk equal to 375 parts; so that 1000 cubic feet of air, at 32°, become dilated to 1375 cubic feet at 212°. Air, therefore, at the freezing point, expands $\frac{1}{480}$ th part of its bulk for every added degree of heat on Fahrenheit's scale: that is,

480 cubic inches, at 32°, become
481 ——— at 33°,
482 ——— at 34°, &c.

increasing one cubic inch for every degree. A contraction of one cubic inch occurs for every degree below 32°: thus

480 cubic inches, at 32°, become
479 ——— at 31°,
478 ——— at 30°, &c. (GRAHAM.)

Air, therefore, at 32° has its volume doubled at 480°, and tripled at 960°: the latter temperature is about that of a dull red heat. Steam, and all other vapours, when heated out of contact of their respective fluids, are subject to laws of expansion similar to those of air. The following table shows the changes of bulk suffered by 100,000 parts of air at all temperatures between 32° and 212°.

Temp.	Bulk.	Temp.	Bulk.	Temp.	Bulk.	Temp.	Bulk.	Temp.	Bulk.
32°	100000	49°	103536	65°	106864	81°	110192	97°	113520

48	103333								

The rate of expansion of atmospheric air at temperatures *above* 212° has been investigated by Dulong and Petit (*Ann. de Chim. et Phys.*, vii. 120). The following table exhibits the results of their observations.

Temperature by the Mercurial Thermometer.		Corresponding Volumes of a given Volume of Air.
Fahr.	Centig.	
— 33	— 36	0·8650
32	0	1·0000
212	100	1·3750
302	150	1·5576
392	200	1·7389
482	250	1·9189
572	300	2·0976
680	360	2·3125

The dilatation suffered by air, when heated, being very considerable, is, of course, attended by a proportionate diminution in the specific gravity or relative weight of the heated portion, which ascends through the colder mass, and excites currents and agitations in the general bulk of air. These currents generally escape observation, in consequence of the invisibility of air; but they may easily be rendered evident; and often excite attention by their violence, as when powerful draughts and wind are produced. The smoke-jack is put into motion by the force of the current of air which passes up the chimney.

In consequence of the relative *lightness* of heated air, it always rises to the upper parts of rooms and buildings, when it either escapes, or, becoming cooled and relatively *heavier*, again descends. If, in cold weather, we sit under a skylight in a warm room, a current of cold air is felt descending upon the head, whilst warmer currents, rising from our bodies, and coming into contact with the cold glass, impart to it their excess of heat. Being thus contracted in bulk, and rendered specifically heavier, they, in their turn, descend, and thus a perpetual motion is kept up in the mass of air. This effect is attended with much inconvenience to those who inhabit the room, and is in great measure prevented by the use of double windows, which prevent the rapid cooling and production of troublesome currents in the air of the apartment.

We generally observe, when the door of a room is opened, that there are two distinct currents in the aperture, which may be rendered evident by holding in it the flame of a candle. At the upper part it is blown outwards, but inwards at the lower part; in the middle, scarcely any draught of air, one way or other, is perceptible.

The art of *ventilating* rooms and buildings is, in a great measure, dependent upon the currents which we are enabled to produce in air by changes of temperature, and is a subject of considerable importance. As the heated air and effluvia of crowded rooms pass upwards, it is common to leave apertures in or near the ceiling for their escape. Were it not, indeed, for such contrivances, the upper parts of theatres and of some other buildings would scarcely be endurable; but a mere aperture, though it allows the foul air to escape, in consequence of its specific lightness, is also apt to admit a counter-current of denser and cold air, which pours down into the room. This effect is prevented by heating, in any convenient way, the tube or flue through which the foul air escapes. A constantly ascending current is then established; and whenever cold air attempts to descend, the heat of the flue rarefies and drives it upwards. Thus the different ventilators may terminate in tubes connected with a chimney; or they may unite into a common trunk, which may pass over

a furnace purposely for heating it; or heated air may be sent, by a flue from below, into the space between the roof and ceiling of the room to be ventilated, and it may have free escape by proper apertures.

In some of our theatres, the gas-chandelier is made a very effectual ventilator. It is suspended under a large funnel, which terminates in a cowl outside the roof; and the number of burners heat the air considerably, and cause its very rapid and constant ascent through the funnel, connected with which there may be other apertures in the ceiling of the building. But in these and similar cases, we often observe that the vents are not sufficiently capacious; and the foul air from the house, and from the gas-burners themselves, not being able readily to escape, diffuses itself over the upper part of the building, and renders the galleries hot and suffocating, all which is easily prevented by the judicious adjustment of the size of the ventilating channels to the quantity of air which it is requisite should freely pass through them. The small tin ventilators, consisting of a rotating wheel, which we sometimes see in window-panes, are perfectly useless, though it is often imagined, in consequence of their apparent activity, that they must be very effectual; but the fact is, that a very trifling current of air suffices to put them in motion, and the apertures for its escape are so small as to produce no effectual change in the air of the apartment: they are also as often in motion by the ingress as by the egress of air.

From what has been said, it will be obvious that our common fires and chimneys are most powerful ventilators, though their good services in this respect are often overlooked. As soon as the fire is lighted, a rapid ascending current of air is established in the chimney, and consequently there must be a constant ingress of fresh air to supply this demand, which generally enters the room through the crevices of the doors and windows. When these are too tight, the chimney smokes, or the fire will not draw; and in such cases it is sometimes necessary to make a concealed aperture in some convenient part of the room for the requisite admission of air, or to submit to sitting with a window or door partly open. Any imperfect action of the chimney, or descending current, is announced by the escape of smoke into the room, and is frequently caused by the flue being too large, or not sufficiently perpendicular and regular in its construction. When there is no fire, the chimneys also generally act as ventilators; and in summer there is often a powerful current up them, in consequence of the roof and chimney-pots being heated by the sun, and thus accelerating the ascent of the air. In a well-constructed house, there should be sufficient apertures for the admission of the requisite quantity of air into the respective rooms, without having occasion to trust to its accidental ingress through every crack and crevice that will allow it to pass. These openings may either be concealed, or made ornamental, and, by proper management, may be subservient to the admission of warm air in winter. A few spare flues should also be provided which may be used either for the egress or ingress of air, independent of the chimneys, as occasion may require.

The manner in which heat is distributed through our apartments by the fires in common use will be noticed afterwards; but large rooms are not uncommonly warmed by heated air, admitted usually through apertures

in the floor. This system is convenient, effective, and agreeable, when properly managed, but this is seldom the case. The rooms are close and oppressive, because due *ventilation* is not associated with the admission of the hot air; the apertures by which the air is admitted are generally too small, and the air itself overheated: the openings should be, according to circumstances, either large, or very numerous, and the *quantity* of air thrown in should be *considerable*, but its *temperature moderate*. In this way the bad smell produced by burnt particles of dust is avoided, and an agreeable freshness, as well as temperature, kept up in the air.

§ 5.—OF THE DETERMINATION OF SPECIFIC GRAVITIES.

FROM the changes of bulk which bodies sustain when they change their temperature, it is obvious that their relative *densities* or *specific gravities* will be liable to proportionate changes; hence chemists are in the habit of referring these to the mean temperature of 55° or 60° , and as the bulk of æriform bodies is also subject to change by increased or diminished pressure, their densities are compared not only at mean *temperature*, but also at mean *barometrical pressure*.

By the term *specific gravity*, we mean the ratio of *weight* to *bulk*; the object, therefore, of the processes for ascertaining it, is either to determine the *weight of a known bulk*, or the *bulk of a known weight*; for whether the substances be reduced to the same weight, and then measured, or to the same bulk, and then weighed, the ratio of their weights to their bulks will be discovered. If reduced to the same bulk, and weighed, their specific gravities will be *directly* as the weights; if reduced to the same weight and measured, their specific gravities will be *inversely* as their bulks. Suppose a like bulk of each kind of matter in nature to be weighed, the results, numerically stated, would represent their specific gravities. But as this would be inconvenient, and often impossible, another method of reducing their bulks to a common measure is resorted to; and, in the case of solids and liquids, the specific gravity of pure water is assumed as the unit to which their specific gravities are compared. On dividing the weight, for instance, of any bulk of the metal *zinc* by the weight of a like bulk of water, the quotient is 7; this, therefore, is said to be the specific gravity of zinc. Proceeding in the same way with *silver*, the quotient is 10·47; with *gold*, 19·3; with *potassium*, 0·86; with *sulphuric acid*, 1·85; with *alcohol*, 0·80: hence these numbers are considered as representing the specific gravities of those bodies; that is, they are their relative weights to water, all being of the same temperature. To obtain the specific gravity, therefore, of a body, we divide its weight by the weight of a quantity of pure water equal to it in bulk, and this we determine as follows:—

We use a delicate balance*, so contrived as to admit of substances

* Balances fitted up for the purpose of ascertaining specific gravities are sold by the philosophical instrument makers: in regard to their use, and the precautions requisite in the various steps of the process, see FARADAY'S *Manipulation*, § II.

“Equality in the length of the arms of

the lever is, of course, the most important consideration in the construction of the balance; but when there may be any reason to doubt this essential point, it is well to know that any error may be avoided by the method of *double weighing*. This consists in placing the object whose

being attached to one of the scales by means of a horse-hair or a fine thread of silk. The absolute weight of the body thus suspended is then very carefully ascertained: it is next immersed in distilled water, of the temperature of 60° ; and the beam being again brought to an equilibrium, we learn the weight lost by its immersion; or, in other words, we ascertain the weight of its bulk of pure water. We now divide the sum of its absolute weight by that of the weight which it lost in water, and the quotient is its *specific weight*, or gravity, compared with water of the temperature of 60° .

Suppose a substance, weighing 360 grains, to lose 60 by immersion in water, the specific gravity of that substance will be $= 6$; for $360 \div 60 = 6$.

When the substance, whose specific gravity is to be ascertained, is *lighter* than water, it may be suspended with some heavier body, and, having determined the weight of the former in air, and of the latter in water, we fasten them together by means of a fine thread (not so closely as to exclude water from their contiguous surfaces, or to include air-bubbles), and weigh them in water, when it will be found that their aggregate weight will fall short of that of the heavier body. If we now subtract the weight of the lighter body from that of the heavier body, and add the remainder to the weight of the former in air, we obtain the weight of a quantity of water equal in bulk to the lighter body; we then divide the weight of the lighter body in air by this last-mentioned sum, and the quotient is its specific gravity.

"A piece of elm wood, having been varnished over to prevent its absorbing water, was found to weigh 920 grains in *air*; a piece of lead, chosen as the ballast, was ascertained to weigh 911.7 grains in *water*; the elm and lead were then tied together, and were found to weigh, in *water*, only 331.7 grains, being 580 grains less than the weight of the lead alone; therefore 580 were added to 920, that is, to the weight of the elm in air, which made up the sum of 1500: lastly, 920 were divided decimally by 1500, and the quotient, .6133, gave the specific gravity required."—Dr. PARIS: *Med. Chem.* 9.

When the substance, whose specific gravity is required, is *soluble* in water, some other fluid, of known specific gravity, must be used, which does not act upon it; alcohol, oil of turpentine, or olive oil, may, in most instances, be used, or in some cases the substance may be coated with varnish. When the substance is in *powder*, it may generally be weighed in a specific-gravity bottle.

For ascertaining the specific gravity of liquids, we usually employ a thin phial, holding 1000 grains of distilled water, at the temperature of 60° . If filled with any other liquid, and weighed, we learn its specific gravity; thus we should find that it would contain 13,500 grains of mercury; 1845 grains of sulphuric acid; 1420 grains of nitric acid, &c., which numbers of course represent the specific gravities of those liquids.

weight is to be ascertained in one scale-pan and exactly counterbalancing it in the other, not with the weights, but with sand or shot, or any other indifferent substance. The substance is then removed, and the weights applied in the same pan till the counterpoise is ba-

lanced. By this contrivance the unknown quantity of matter is compared with the known, under exactly equal circumstances, and the result is independent of almost every source of error which can affect the comparison of one object with another."—DANIELL, § 32.

A bottle, however, holding 1000 grains, is often inconveniently large, and a small and thin globular phial, with a piece of thermometer-tube ground into it by way of stopper, will be found more useful: such a phial should not weigh more than from 50 to 60 grains, and may contain between 400 and 500 grains of water. To use it, it should be accurately counterbalanced in a delicate pair of scales, and then filled with distilled water, and the stopper thrust in, the capillary opening in which allows a little to ooze out, and prevents the likelihood of bursting the phial; it is then to be wiped clean and dry, and again carefully weighed, by which the quantity of water it contains is ascertained; the water being poured out, it is next filled with the liquid whose specific gravity is required, taking care that it is of the same temperature as the water; we then weigh as before, and divide the weight of the liquid by the former weight of water; the product gives the specific gravity required. Thus, suppose the phial to contain 425 grains of water at the temperature of 60° , it will be found to hold 5737·5 grains of pure mercury of the same temperature; and $5737\cdot5 \div 425 = 13\cdot5$, the specific gravity of mercury. Or, supposing the liquid lighter than water, such as alcohol, of which we may assume the phial to contain 350·5; then $350\cdot5 \div 425 = 0\cdot824$, the specific gravity of the alcohol under trial.

We also, in determining the specific gravity of fluids, frequently employ the *hydrometer*; but it cannot be resorted to where great accuracy is required. Where, however, a number of specific gravities are to be quickly determined, as in respect to spirituous liquors for the purpose of levying duties, or in certain processes of the arts, these instruments, from the facility of their application, become indispensable.

The determination of the specific gravity of air, and of different gases, will be described under the article *Atmospheric Air*, as it involves several circumstances not yet adverted to.

§ 6.—THERMOMETERS AND PYROMETERS.

HAVING stated some of the general effects of contraction and expansion, we may now proceed to the examination of the *thermometer*—an instrument of considerable importance in researches connected with the subject of heat.

The first instrument to which the term *thermometer* (from *θερμος*, *heat*, and *μητρον*, *a measure*) can properly be applied, was apparently invented by the Florentine Academicians, about the middle of the seventeenth century. It consisted of a glass tube, with a bulb or ball blown at one extremity, fig. 65, and filled up to a certain mark, with spirit of wine; the expansion of which, or its rise above the mark, indicated *heat*, and its contraction, or fall below the mark, *cold*. They afterwards placed a number of little equidistant studs of white enamel on the tube, rendering the expansions and contractions of the confined liquid more evident; and by these they sometimes divided it into a hundred parts or degrees. Such instruments were first introduced into England by Boyle. For a long time, no one would believe that a liquid could contract and expand in a tube closed at both ends; but Boyle soon satisfied himself of the

fact by experiment, and by the inspection of the *Florentine glasses*, for so these instruments were then called. About the beginning of the eighteenth century, a considerable improvement was made in this original thermometer, by Fahrenheit, of Amsterdam, who, by the use of mercury instead of alcohol, was enabled greatly to diminish the size of the tube and bulb, and to measure comparatively high degrees of temperature.

But all these instruments laboured under the serious defect of entire want of agreement with each other: the division of the tube was founded on no fixed principle, but was arbitrary, and differently constructed and applied in every thermometer. It required no common ingenuity to overcome this difficulty, and to construct instruments which should agree with each other when exposed to the same temperature. This, however, was at length effected by a suggestion of Sir Isaac Newton, founded upon a discovery of Dr. Hooke, who observed, that when a thermometer-tube, properly filled with mercury, was plunged into melting ice or snow, the liquid metal always contracted, or fell to a certain point, at which it remained perfectly stationary till all the ice was melted. If we now mark this point upon the tube, it will be found that, whenever it is subjected to the same experiment, the quicksilver falls exactly to the same level or point, and hence this point may be called the *melting-point of ice*; and it has since been ascertained that this is also precisely the point at which water, under ordinary circumstances, freezes, so that it is also called the *freezing-point of water*. Here, then, a part at least of the difficulty above adverted to is removed, and *one* fixed point for thermometric graduation ascertained.

Dr. Hooke afterwards made a similar discovery in regard to boiling water, which, under ordinary circumstances, he found always exhibited one and the same degree of heat. If, therefore, we now plunge the thermometer, upon which the freezing-point of water has already been marked, into an open vessel of water placed upon the fire or over a lamp, we shall observe the mercury continue to rise in the tube until the water boils, when it becomes quite stationary, and the point may be marked as before. Now it will be found, that whenever this thermometer is put into boiling water, the mercury will rise to the same height*. Here, then, we have a *second* determinate point, namely, the *boiling-point of water*; and it is now obvious, that if we divide the space of the tube between these two fixed points into any given number of degrees, the mercury will indicate the same degree in all bodies of one and the same temperature; and that any number of thermometers, carefully constructed upon this principle, will agree with each other in their indications of temperature.

The space between the boiling and freezing of water has often been divided into *one hundred* equal parts—the freezing point being marked 0° , and the boiling-point 100° . This is commonly called the *centigrade scale*; it originated with Celsius in Sweden, and is used in France and many other parts of Europe. *Reaumur's scale* calls the freezing-point 0° , and the boiling-point 80° , and is employed in most parts of Germany

* Some circumstances affect the boiling-point, such as the state of the barometer or of the pressure of the atmosphere, and the nature of the vessel in which the experiment is made. We presume above that the barometer stands at thirty inches, and that the vessel is of thin metal.

and Italy. In this country we generally refer to *Fahrenheit's scale*, which sets out at the temperature produced by mixing snow with salt, which is 32° below the freezing of water; and the space between that and the boiling-point being divided into 180° , the latter is called 212° . In all these scales, the graduation is continued below 0° in the same way as above it. These are called *degrees below 0°* , and are generally distinguished by prefixing the mark ($-$) *minus* before them: thus -10° means ten degrees below 0° ; sometimes the mark ($+$) *plus* is prefixed to the degrees above zero, as $+10^{\circ}$, or ten degrees above 0° .

Each degree of Fahrenheit's scale is equal to $\frac{4}{9}$ of a degree on Reaumur's: if, therefore, the number of degrees of Fahrenheit's scale, above or below the freezing of water, be multiplied by 4, and divided by 9, the quotient will be the corresponding degree of Reaumur.

Fahrenheit.	Reaumur.
$68^{\circ} - 32^{\circ} = 36 \times 4 = 144 \div 9 = 16^{\circ}$	
$212^{\circ} - 32^{\circ} = 180 \times 4 = 720 \div 9 = 80^{\circ}$	

To reduce the degrees of Reaumur to those of Fahrenheit, they are to be multiplied by 9, and divided by 4.

Reaumur.	Fahrenheit.
$16^{\circ} \times 9 = 144 \div 4 = 36^{\circ} + 32^{\circ} = 68$	
$80^{\circ} \times 9 = 720 \div 4 = 180^{\circ} + 32^{\circ} = 212$	

Every degree of Fahrenheit is equal to $\frac{5}{9}$ of a degree on the Centigrade scale; the reduction, therefore, is as follows:—

Fahrenheit.	Centigrade.
$212 - 32 = 180 \times 5 = 900 \div 9 = 100^{\circ}$	
Centigrade.	Fahrenheit.
$100 \times 9 = 900 \div 5 = 180 + 32 = 212^{\circ}$	

The annexed scale, including De Lisle's thermometer, which is sometimes used in Russia, and in which the boiling point is marked 0° , and the freezing 150° ; and the following table of Fahrenheit's degrees compared with those of the Centigrade and Reaumur's scale, will save the trouble of their calculation.

TABLE OF THE CORRESPONDING DEGREES ON THE SCALES OF FAHRENHEIT, REAUMUR, AND CELSIUS, OR CENTIGRADE. (From Warrington's Tables.)

Fahr.	Reau.	Cent.	Fahr.	Reau.	Cent.	Fahr.	Reau.	Cent.
212	80	100	149	52	65	50	8	10

10		-30	
0	-20		

It is very much to be regretted that, for want of a little exertion and unanimity amongst the philosophers of Europe, these discrepant thermometric scales are so inconveniently retained: the Centigrade scale is perhaps that which it would be most convenient generally to adopt. To avoid the inconvenience of the magnitude of its degrees, and the consequent necessity of frequent reference to their fractional parts, a scale has been proposed, the extremes of which are the freezing and boiling points of mercury, the former to be 0° , the latter 1000° . The entire novelty of such a scale is its principal objection.

For all common purposes ordinary thermometers are sufficiently accurate; but the experimental laboratory should be furnished with a *standard thermometer*, very carefully constructed, and with a scale exhibiting the divisions of Reaumur and Fahrenheit, and the Centigrade. Such an instrument of reference is useful to determine the quality of *common* thermometers, no two of which will be found precisely to agree at the different points of the scale. It sometimes happens that a thermometer originally correct will after a time be found to err slightly in excess in its indications of temperature, an effect probably arising from the continued pressure of the atmosphere upon the bulb, by which its bulk is permanently diminished: this may, however, be prevented by giving the bulb a certain degree of thickness, although the sensibility of the instrument to sudden changes of temperature is by this somewhat impaired.

There are numerous and useful varieties in the *forms* of thermometers, which need not be here enumerated in detail. Among them the *self-registering* thermometers are valuable, as showing the maximum and minimum of temperature during the absence of the observer. Many of these instruments which have been suggested, are too complicated or too expensive to be generally useful; but there are two of them which are sufficiently simple, and in common use, namely, Six's thermometer (*Phil. Trans.*, vol. LXXII.); and that contrived by Dr. John Rutherford (*Edinb. Phil. Trans.*, vol. iii.).

That the degrees of the thermometer actually represent equal degrees or increments of heat, is shown by a simple experiment originally suggested by Dr. Brook Taylor. It consisted in mixing together, with due precaution, equal parts of hot and cold water; and it was found that the thermometer, applied to such a mixture, indicated the arithmetical mean between the extremes. Thus, if we mix a pound of water at the temperature of 200° with a pound at the temperature of 100° , an accurate thermometer will show in the mixture the *mean* temperature of 150° .

PYROMETERS.—The indications of the mercurial thermometer are obviously limited within the freezing and boiling points of mercury. It congeals at -39° , and boils at $+662^{\circ}$; and on the moment of its congelation it shrinks so remarkably, as to have led early experimentalists into considerable errors as to the actual cold required for the purpose. When it boils, its vapour, of course, bursts the tube. Although, therefore, the range of temperature which may be accurately measured by the expansion and contraction of mercury is very extensive, it is often requisite to measure degrees of cold below its freezing-point, and of heat above its boiling-point. Pure spirit of wine, or *alcohol*, has never been frozen,

and it is consequently used in those thermometers which are intended to indicate excessive degrees of cold; but no fluid has yet been found applicable to the construction of a thermometer capable of indicating higher temperatures than mercury. When, therefore, a degree of heat approaching to, or exceeding dull redness, is to be measured, other methods and substances must be resorted to: instruments constructed for this purpose are called *pyrometers*, from *πυρ*, *fire*, and *μετρον*, *a measure*.

Of these instruments, that suggested by Mr. Daniell seems the least exceptionable, and is not liable to those sources of fallacy which render the results obtained by *Wedgwood's clay pyrometer* so uncertain and equivocal*. The following is Mr. Daniell's description of his *Register pyrometer*. (*Introd. to Chem. Phil.*, § 146.)

"It consists of two parts, which may be distinguished as the register and the scale. The *register* is a solid bar of black-lead earthenware, highly baked. In this a hole is drilled, into which a bar of any metal, six inches long, may be dropped, and which will then rest upon its solid end. A cylindrical piece of porcelain, called the index, is then placed upon the top of the bar, and confined in its place by a ring or strap of platinum passing round the top of the register, which is partly cut away at the top, and tightened by a wedge of porcelain. When such an arrangement is exposed to a high temperature, it is obvious that the expansion of the metallic bar will force the index forward to the amount of the excess of its expansion over that of the black-lead, and that, when again cooled, it will be left at the point of greatest elongation. What is now required, is the measurement of the distance which the index has been thrust forward from its first position; and this, though in any case but small, may be effected with great precision by means of the *scale*.

"This is independent of the register, and consists of two rules of brass, accurately joined together at a right angle by their edges, and fitting square upon two sides of the black-lead bar. At one end of this double rule a small plate of brass projects at a right angle, which may be brought down upon the shoulder of the register, formed by the notch cut away for the reception of the index. A moveable arm is attached upon this frame, turning at its fixed extremity upon a centre, and at its other, carrying an arc of a circle, whose radius is exactly five inches, accurately divided into degrees and thirds of a degree. Upon this arm, at the centre of the circle, another lighter arm is made to turn, one end of which carries a nonius with it, which moves upon the face of the arc, and subdivides the former graduation into minutes of a degree; the other end crosses the centre, and terminates in an obtuse steel point, turned inwards at a right angle.

"When an observation is to be made, a bar of platinum, or malleable iron, is placed in the cavity of the register, the index is to be pressed down upon it, and firmly fixed in its place by the platinum strap and porcelain wedge. The scale is then to be applied by carefully adjusting the brass rule to the sides of the register, and fixing it by pressing the cross piece upon the shoulder, and placing the moveable arm, so that the steel point of the radius may drop into a small cavity made for its

* This pyrometer may now be considered as obsolete. It is described in | the *Philosophical Transactions*, vols. LXXii, LXXiv, LXXvi.

reception, and coinciding with the axis of the metallic bar. The minute of the degree must then be noted, which the nonius indicates upon the arc. A similar observation must be made after the register has been exposed to the increased temperature which it is designed to measure, and again cooled, and it will be found that the nonius has been moved forward a certain number of degrees or minutes. The scale of the pyrometer is readily connected with that of the thermometer by immersing the register in boiling mercury, whose temperature is as constant as that of boiling water, and has been accurately determined by the thermometer. The amount of expansion for a known number of degrees is thus determined, and the value of all other expansions may be considered as proportional.

"The melting point of cast iron has been thus ascertained to be 2786° , and the highest temperature of a good wind furnace about 3300° ; points which were estimated by Mr. Wedgwood at 20577° and 32277° respectively.

"Fig. 66 represents the register; A is the bar of black-lead; $a a'$ the cavity for the reception of the metal bar; $c c'$ is the index, or cylindrical piece of porcelain; d the platinum band, with its wedge, e .

"Fig. 67 is the scale by which the expansion is measured; $f f'$ is the greater rule upon which the smaller, g , is fixed square. The projecting arm, h , is also fitted square to the ledge, under the platinum band, d . D is the arm which carries the graduated arc of the circle fixed to the

rule, ff' , and moveable upon the centre, i . c is the lighter bar, fixed to the first, and moving upon the centre, k . l is a small lens, folded back upon the arm, by which, when erected, the divisions may be accurately read off. H is the nonius at one of its extremities, and m the steel point at the other."

AIR-THERMOMETERS.—Sometimes the expansions and contractions of *air*, which, as already stated, are relatively great for small changes of temperature, are resorted to in delicate experiments, in which slight variations of heat require to be indicated. The simplest form of the *air-thermometer* consists of a tube with a thin bulb at its upper end, and dipping at the lower end and open extremity into a little coloured fluid, fig. 68; some of the air is then expelled by the heat of the hand, so that, as the bulb cools, the liquid may rise to about half way up the tube. This instrument is very sensible to slight changes of temperature: heat expands the air in the bulb, and drives the fluid downwards; and cold, by contracting the air, causes the fluid to rise.

This was one of the first forms of the thermometer that was invented, and is only inconvenient from its extreme delicacy, and the great length of tube required to measure any considerable range of heat and cold.

Another and much more useful form of air-thermometer is represented in the wood-cut, fig. 69: it has sometimes been called the *differential thermometer*. It consists of two

bulbs, a and b , containing air, united by a tube twice bent at right angles, in which there is a little coloured sulphuric acid: the tube is supported upon a wooden foot or stand. When a hot body is brought near one of the bulbs, it expands the air within it, and drives the fluid towards the other; from b , for instance, to a . One of the chief advantages of this air-thermometer is, that it is not affected by any general changes in the temperature of the surrounding air, because they act equally on both bulbs, and occasion no motion of the included column of liquid; but when one of the bulbs is exposed to any source of heat which does not affect the other, the *difference* of temperature between the two bulbs is immediately and very sensibly indicated by the

recession of the fluid from the heated towards the cold bulb. The advantages of this instrument will be more evident when some of its practical applications are afterwards pointed out*.

The following table from Professor GRAHAM'S *Elements of Chemistry* will give an idea of the range of temperature within which certain points have been accurately determined: the degrees are those of Fahrenheit's scale.

Greatest artificial cold produced by Thilorier	- 135°	Ice melts	+ 32°
Solid compound of alcohol and carbonic acid fuses	- 131	Medium temperature of the surface of the globe	+ 50
Greatest artificial cold produced by Walker	- 91	Medium temperature of England	+ 52
Temperature of planetary space (Fourier)	- 58	Heat of human blood	+ 98
Greatest natural cold observed by Ross	- 60	Pyroligneous spirit boils	+ 150
Ditto by Parry	- 55	Alcohol boils	+ 174
Sulphuric ether congeals	- 47	Water boils	+ 212
Mercury freezes	- 39	Tin melts	+ 442
Proof spirit freezes	- 7	Lead melts	+ 594
Mixture of 1 part of alcohol and 3 of water freezes	+ 7	Mercury boils	+ 662
Strong wine freezes	+ 20	Red Heat (Daniell)	+ 980
		Heat of common fire (do.)	+ 1140
		Brass melts (do.)	+ 1869
		Silver melts (do.)	+ 2233
		Iron melts (do.)	+ 3479

§ 6.—CONDUCTION OF HEAT.

WE have already seen (page 140) how easily heat is diffused through liquids by change of density, and that its propagation through æriform bodies is often dependent upon a similar mode of transfer (p. 142). When heat traverses *solid* bodies its passage is altogether of a different character; it suffers great retardation, and is said to be *conducted*.

It has been observed by Sir J. Herschel (*Discourse on the Study of Natural Philosophy*, p. 206), that as the particles of the most solid bodies are not absolutely in contact, conduction, when properly considered, is merely a case of radiation, and "that if we would rightly understand what is the process of nature in this slow communication of heat through the substance of a solid, we must ground our inquiries upon what takes place at a distance, and then urge the laws to which we have arrived up to their extreme case." This mutual dependence of the laws of conduction and radiation will be again adverted to when considering the latter mode of the propagation of heat. We are, however, too little acquainted with the minute corpuscular structure of bodies, to know what goes on between particle and particle, in apparent contact; and the bad radiating, yet good conducting power of the metals, apparently shows that these are distinct modes of the propagation of heat.

CONDUCTION BY SOLIDS.—A rod or bar of metal is well calculated to illustrate this conduction of heat: if one end of it be held in the candle, and the other in the hand, the heat gradually and progressively makes its way from one end to the other; if the hand be near the source of heat, or the bar short, it soon becomes too hot to hold. This slow pro-

* There is a useful treatise on the | and pyrometers in the Library of Useful
various constructions of thermometers | Knowledge. *Natural Philos.*, vol. ii.

gress of heat along the bar is well shown by attaching several bullets or wooden balls to the side of a square bar of metal 18 or 20 inches long, at intervals of about two inches apart, by a little wax, and then heating one end of the bar over a lamp: (fig. 70.) the balls successively drop off as the heat finds its way along the bar. If we employ bars of *different* metals, it will be found that some conduct heat better than others: thus, if two similar wires, one of platinum and one of silver, be heated at one end, the heat will pervade the silver much more rapidly than the platinum; and if cones of several metals, like the one represented in fig. 71, be respectively tipped with a small piece of wax, and placed upon a heated plate of metal, the wax will melt at different periods upon the different cones, thus showing their different conducting powers.

Gold, silver, copper, and tin, are the best conductors, and nearly equal; iron, platinum, and lead, are much inferior. (INGENHOUSZ, *Jour. de Phys.*, 1789, p. 68; DESPRETZ, *Ann. de Ch. et Ph.*, vol. xxxvi., p. 422.) It does not appear, therefore, that the conducting power corresponds either with the density, the tenacity, or the fusibility of the metals. In these cases of conduction the following law is observed: if the extremity of a metallic bar be placed in communication with a constant source of heat, and we wait till it has taken up a permanent state of temperature, we shall find that for distances from the source, taken in arithmetical progression, the excess of temperature above the surrounding medium will form a geometrical progression.

Next to metals, the diamond, the topaz, and some earthy compounds, appear to have the greatest conducting power: then stony bodies, porcelain and glass, and porous earthy compounds, such as earthenware and bricks. Wood is a very bad conductor of heat; so is charcoal; and these may be held, without burning the fingers, very near the red-hot part.

The following table from the experiments of Despretz, (*Ann. de Ch. et Ph.* xxxvi., p. 422), represents the conducting powers of several substances compared with gold.

Gold 1000	Platinum . . . 381	Tin 304	Porcelain . . . 12
Silver 973	Iron 374	Lead 180	Fine clay . . . 11
Copper 898	Zinc 363	Marble 24	

From the experiments of Mayer, of Erlangen, (*Ann. de Ch.*, xxx.,) it would appear that the conducting powers of different woods is in some measure inversely as their specific gravities, as shown by the following table, but water is not a very intelligible standard of reference.

	Conducting Power.	Specific Grav.		Conducting Power.	Specific Grav.
Water	10 . . .	1.000	Oak	32.6 . . .	0.668
Ebony wood . . .	21.7 . . .	1.054	Pear tree	32.2 . . .	0.603
Apple tree . . .	27.4 . . .	0.639	Birch	34.1 . . .	0.608
Ash	30.3 . . .	0.631	Silver fir	37.5 . . .	0.495
Beech	32.1 . . .	0.692	Alder	38.4 . . .	0.484
Hornbeam	32.3 . . .	0.690	Scotch fir	38.6 . . .	0.408
Plum tree	32.5 . . .	0.687	Norway spruce . .	38.9 . . .	0.447
Elm	32.5 . . .	0.646	Lime	39.0 . . .	0.408

Porous substances used in clothing, and the natural coverings of most animals, are also bad conductors of heat; but in these and similar cases interstitial air cannot be excluded, and consequently their true conducting power is not accurately determinable. Count Rumford found that when a heated thermometer, surrounded by about an inch in thickness of confined air, took 576 seconds to cool 135° , it took 1032 seconds to cool to the same point when 16 grains of *lint* were diffused through the confined air, and 1305 seconds when the same weight of *eiderdown* was used; so that the conducting power being inversely as the times, if the power of air be = 1000, that of the lint will be = 558, and of the eiderdown = 441. The conducting power of these substances is further diminished by the closeness with which their particles are compressed, provided, that is, their texture is not too closely compacted: thus, when the same space, which in the above experiment was occupied by 16 grains of eiderdown, was filled first with 32 grains, and then with 64, the times employed in the escape of the heat from the enveloped thermometer were successively increased from 1305 seconds to 1472 and 1615 seconds.

To show the influence of mere *texture* upon conducting power, similar trials were made with raw silk, ravelings of white taffeta, and of common sewing silk; of which the first has the finest fibre, the second less fine, and the third, from being twisted and harder, is much coarser. The difference between these three modifications of the same substance was very striking; the raw silk detaining the heat for 1284 seconds, the taffeta ravelings 1169 seconds, and the silk thread only 917 seconds. *Phil. Trans.*, 1792.

The application of these facts to the retention of the natural heat of the body by different kinds of clothing, is sufficiently obvious; and it is evident that, as far as mere conducting power of animal and vegetable substances is concerned, the worst conductors are those in which the fibres are finest and least condensed. There are, however, other circumstances which interfere in these applications, and which will be more intelligible when the subject of *radiation of heat* is under consideration.

CONDUCTION BY LIQUIDS.—Liquids are very imperfect conductors of heat, and have frequently been regarded as absolute non-conductors; the same remark applies to gaseous or æriform bodies. It has already been shown (page 140), that in the usual mode of heating liquids, the heat is applied to the *bottom* of the vessel containing them, and is diffused over the whole mass in consequence of successive *changes of density* in the heated portion; the warm currents which are thus established ascend, and the cold ones descend, and this motion is kept up till the water boils. If, however, we apply heat to the *surface* of the water, the heat can only be propagated downwards by its *conducting power*; for the heated portion, being lighter than the colder water beneath, floats upon its surface, and no interchange of strata, analogous to that previously described, can possibly ensue. It may thus be shown that it is almost impossible to transmit heat through water or other fluid by its mere conducting power. The following, among other experiments, may be selected in illustration:—Let *a*, fig. 72, represent a cylindrical vessel of water with an included air-thermometer, the bulb of which very nearly reaches the surface:

b is a small copper basin floating upon the surface, the bottom of which is only separated from the bulb of the air-thermometer by a very thin stratum of water: if some inflamed ether or alcohol, or a little glowing charcoal, be now put into the basin, the surface of the water may be heated to its boiling-point, and yet scarcely any elevation of temperature will be indicated by the neighbouring thermometer; and it will be impossible to transmit the heat from the surface downwards. In this way of making the experiment, it is obvious that some heat may be conveyed by the sides of the vessel; but as glass is a bad conductor, this source of error is comparatively small, and only produces an effect when the heat on the surface is long continued.

The following is a mode of illustrating the

bad conducting power of another liquid—namely *oil*. *a*, fig. 73, represents a thin glass tube about two feet in length, closed at one end, and open at the other: pour into it a couple of inches of water, and freeze it by immersion in a mixture of salt and ice;

then upon the lump of ice at the bottom, *b*, pour eight or ten inches of oil, *c*, and upon the oil, two or three inches of spirit of wine, *d*. If the portion of the tube containing the spirit be now carefully held over the chimney of a lamp, the spirit may be boiled, and even entirely evaporated, whilst the oil will be little heated, and the ice not thawed.

A good class-experiment upon this subject, where it is necessary that effects should be seen at a distance, may be arranged as follows:—Let *A* (fig. 74) represent an inverted air-jar, which may be supported upon a ring-stand, filled up to the line *B* with cold water. *E* is a long-tubed air thermometer, fitted water-tight into the neck of the jar, the coloured liquid in which stands at about the level *E*, the bulb being surrounded by the cold water. A disc of thin cork nearly fitting *A* is then floated upon the water, and some hot water tinged blue or red is carefully poured up to the level, *c*, the cork disc (pre-

venting its mixture with the cold water beneath) may then be removed, and the hot coloured water remains floating upon the cold colourless water, and no effect is produced upon the thermometer. The syphon, *d*, is now carefully introduced, and the cold water gradually drawn off, so as to allow the hot coloured stratum to descend within a line of the bulb, but it still produces no effect till the hot water touches, and afterwards surrounds, the air-thermometer, when the liquid in its tube immediately descends from *e* into the cup.

These, and a number of similar facts and experiments, show that *water, and other liquids, are very imperfect conductors of heat*; and that fluids acquire and lose heat principally by the currents which have been described (pp. 140, 141), and which always take place in them when partially heated or cooled; the warmer parts ascending, and the colder descending. Whatever impedes these motions will proportionately interfere with the heating and cooling of the fluid. Hence viscid liquids, or those containing substances that mechanically thicken them, are more tardy in their reception and emission of heat than pure water: of this, thick soups afford a familiar example; they are a long time cooling.

The inference which has sometimes been drawn, that the state of liquidity prevents conduction, or the transfer of heat from particle to particle, is negatived, in regard to mercury at least, by substituting that metal for the cold water, in the apparatus, fig. 74; upon pouring hot water upon its surface, the thermometer is presently affected even through a considerable stratum of the fluid metal.

CONDUCTION BY GASES.—The experiments which have been made to determine the *conducting powers of gaseous bodies* are not very satisfactory in their results: and it has as yet scarcely been ascertained whether *air* is, or is not, properly speaking, a *conductor* of heat. A striking illustration of the non-conducting power of *steam* is afforded by carefully dropping a little water into a silver spoon or platinum crucible, heated nearly to redness; the water lies quietly upon the metal so long as it is prevented coming into perfect contact with it by the interposed layer of steam; but as soon as the crucible cools down, so as to admit the water to touch it, it instantly boils off. This explanation is however disallowed by M. Laurent. *Ann. de C. et P.*, lxii. 327.

When a heated body is suspended in the atmosphere, and freely exposed on all sides to air, it gradually parts with its excess of heat, so as to attain the temperature of the surrounding substances; but this cooling effect is produced by a variety of causes, independent of any real conducting power of the air. We have already alluded to the extreme facility with which currents are formed in air when heated substances are exposed to it: the warm air ascends, and a continual current is produced, which glides over the surface of the heated matter; thus, much heat is conveyed away by the establishment of currents, in consequence of change of density in the air. But heated bodies exposed to air also part with excess of temperature by *radiation*, a process continually going on from their surfaces, and which will presently require our minute attention. Upon the whole, it appears that *air is a very imperfect conductor of heat*.

REMARKS ON THE RELATIVE CONDUCTING POWERS OF BODIES.—It would

appear, from what has been stated, that those bodies which are the best conductors of heat, have the weakest attraction for it, and that bad conductors have the strongest attraction: the former, therefore, part with their heat more readily than the latter. Metals, which are excellent conductors, are easily heated, and as easily give out their heat. It is painful to touch metal heated to about 120° . Water scalds at 150° ; but air may be heated to 250° , or even 300° , without being painful to our organs of sensation. Sir F. Chantrey has a large stove, or oven, for drying the moulds employed in his bronze castings; a thermometer suspended in it generally stands at about 300° : the workmen enter and remain in it for some minutes without much inconvenience; and a person wholly unused to such high heats may walk into and out of it with impunity, though, to such, any attempt to remain generally occasions difficult breathing, and a painful sensation about the eyes, but the skin remains parched and dry. In subjecting ourselves to atmospheres thus highly heated, it is necessary carefully to avoid the contact of any good conductor of heat: if we touch a piece of metal, it would inevitably burn us; and a person once inadvertently entered with his spectacles on; which, being mounted in silver, presently burned the points of contact with his face.

The relative conducting powers of metal and wood are familiarly illustrated in the application of wooden handles to metallic vessels intended to contain hot liquids; or, sometimes, where the handle is required to be of metal, a thin piece of wood or ivory is interposed between it and the body of the vessel, by which all rapid communication of heat is effectually cut off.

We avail ourselves of the bad conducting power of brick and stone, in the construction of furnaces intended to retain their interior heat; but where the object is to communicate heat to the surrounding air, and not to retain it in the body of the furnace, they are made of cast or wrought iron, and the lining of brickwork is dispensed with, so that the heat may readily find its way outward.

A remarkable instance of the bad conducting powers of the earthy bodies constituting volcanic ashes is cited by Mr. Lyell, (*Principles of Geology*), in the preservation of a glacier near the summit of Etna, in consequence of its having been covered by volcanic dust, over which a current of lava afterwards flowed. He supposes that at the commencement of the eruption a deep mass of drift snow had been covered by volcanic sand showered down upon it before the descent of the lava. "A dense stratum of this fine dust," he says, "mixed with scorïe is well known to be an extremely bad conductor of heat, and the shepherds in the higher regions of Etna are accustomed to provide water for their flocks during summer, by strewing a layer of volcanic sand a few inches thick over the snow, which effectually prevents the heat of the sun from penetrating. Suppose the mass of snow to have been preserved from liquifaction until the lower part of the lava had consolidated, we may then readily conceive that a glacier thus protected, at the height of 10,000 feet above the level of the sea, would endure as long as the snows of Mont Blanc, unless melted by volcanic heat from below."

Charcoal is among the very worst conductors of heat; and there is a

well-known experiment which illustrates this, consisting in placing a tea-kettle of boiling water just taken from the fire, upon the palm of the hand: it is, of course, essential to its success that the bottom of the kettle should be well covered with soot, which is a porous form of charcoal, and effectually prevents the transmission of heat from the water within to the hand. So also when the palm of the hand is covered by a layer of dry sand, or of fine asbestos, a red-hot iron ball may be placed upon it with impunity.

The comparative conducting power of wood and metal is also well illustrated by the following experiment: take a smooth round bar of brass, or other *metal*, about an inch in diameter, and ten or twelve in length, and stretch a strip of writing-paper tightly over a part of it, to which apply the flame of a candle or spirit lamp, and it will be found impossible to burn or even singe the paper; for the heat passes through it to the metal, and is conducted away so rapidly, that its accumulation, or the temperature required to burn the paper, cannot be attained. If we now substitute a *wooden* bar of the same dimensions as the metallic one, stretch the paper over it, and hold it in the flame, the paper will presently singe and char, and the wood beneath will be inflamed, in consequence of its bad conducting power, which prevents the diffusion of the heat, and concentrates its effects upon the spot to which the flame is applied.

A stratum of confined air is an extremely bad conductor of heat: hence the advantage, in some instances, of double walls to furnaces, air being confined between them; and to icehouses, to exclude external heat; and of double windows to our apartments, to prevent the transmission of heat, and ingress of cold.

We have shown, that in air, the power of communicating heat is very feeble; its actual power of *abstracting* heat is also proportionably small: in the high northern latitudes, provided the air is tranquil, and there is no wind, a degree of cold may be sustained without injury, in which mercury freezes; but if, in this state of the atmosphere, *metallic* substances be touched, of the same low temperature, a sensation like that of burning is experienced, and the part becomes blistered.

We have above adverted to the effects of a high temperature upon the human body. The opposite effects of a very low temperature cannot be commanded artificially, and, therefore, opportunities seldom occur of witnessing them so as minutely to observe their consequences. Captain Parry and his associates, in their *Voyage for the Discovery of a North-west Passage*, frequently experienced a degree of atmospheric cold below the freezing of mercury. Under the date of Tuesday, the 15th of February, 1820, he says, "From four p.m., on the 14th, till half-past seven on the following morning, being an interval of fifteen hours and a half, during which time the weather was clear, and nearly calm, a thermometer, fixed on a pole between the ships and the shore, never rose above -54° , and was once, during that interval, namely, at six in the morning, as low as -55° . This low temperature might perhaps have continued much longer, but for a light breeze which sprung up from the northward, immediately on which the thermometer rose to -49° , and continued still to rise during the day, till, at midnight, it had reached

—34°. During the lowest temperature above mentioned, which was the most intense degree of cold marked by the spirit-thermometer during our stay in Winter Harbour, not the slightest inconvenience was suffered from exposure to the open air by a person well clothed, as long as the weather was perfectly calm; but in walking against a very light air or wind, a smarting sensation was experienced all over the face, accompanied by a pain in the middle of the forehead, which soon became rather severe. We amused ourselves in freezing some mercury during the continuance of the cold weather, and by beating it out on an anvil previously reduced to the temperature of the atmosphere; it did not appear to be very malleable when in this state, usually breaking after two or three blows of the hammer."

§ 7.—CAPACITIES FOR HEAT. SPECIFIC HEAT.

UNDER these terms we shall consider the relation of the *temperature* of bodies, whilst in the same state or form, to the *quantity of heat* contained in them. That the thermometer is an accurate measurer of temperature has been shown by Dr. Taylor's experiment already quoted, but, as was first proved by Dr. Black in his lectures at Glasgow, in 1762, it affords no correct insight into the *absolute quantity of heat necessary to produce a given temperature*: if, for instance, a pound of olive oil and a pound of water be brought from a cold into a warm room, from a temperature perhaps of 40° to a temperature of 70°, they will, it is true, gradually acquire the same temperature; and thermometers immersed in the respective liquids will gradually rise from 40° to 70°; but if we carefully watch the manner in which this rise of temperature is brought about, we shall find that the oil acquires the temperature of 70° more rapidly than the water; whence the inference, that the oil requires less heat to raise it from 40° to 70° than the water. Again, if we reverse the experiment, and transfer the two liquids from a warm to a cold room, it will then be observed that the oil cools more rapidly than the water: the fact is, that the quantity of heat required to raise water from 40° to 70° is much greater than that required to raise the oil a similar number of thermometric degrees, and consequently oil is more rapidly heated and cooled than a corresponding quantity of water. The following experiment proves this to be the case. A pound of *water* at 212° was surrounded, in a proper apparatus*, by ice, and the quantity of ice which was thawed by the heat given out by the water in cooling from 212° to 32°, was ascertained. A similar experiment was then made with the same weight of *oil*, and it was found that, in passing through the same range of temperature, it only thawed half as much ice as the water: although, therefore, the *temperatures* of the liquids were the same at the outset and conclusion of the experiment, the quantity of heat given out by the oil was only half that given out by the water; whence we infer that *bodies, though of the same temperature,*

* The instrument employed for this purpose was contrived by Lavoisier and Laplace, and is fully described in LAVOISIER'S *Elements of Chemistry*: they termed it a *Calorimeter*. Its inaccuracy, resulting from the difficulty of separating the water from the ice, has been shown by Wedgwood.—*Phil. Trans.*, vol. LXXIV.

do not contain the same quantity of heat, some requiring more, and some less heat, to raise them to a given thermometric point. The quantity of heat thus required is called the *specific heat* of the body; and if, in reference to the above statement, we call the specific heat of water 100, that of oil will only be 50; or, in other words, water has twice the *capacity for heat* that oil has.

It has been stated that equal quantities of the same fluid, at different temperatures, give the arithmetical mean, on mixture. Equal measures, for instance, of water at 70° , and of water at 130° , will give the mean temperature of 100° ; that is, the hot water loses 30° , and the cooler water gains 30° . But if equal measures of water at 70° , and of mercury at 130° be mixed, the resulting temperature will not be the mean, or 100° , but only 90° . Here, therefore, the mercury loses 40° , while the water only gains 20° ; hence the inference, that the quantity of heat required to raise a given measure of mercury 100° , will only raise the same measure of water 50° : that is, (speaking here of equal bulks, and not, as in regard to the oil, of equal *weights*;) the capacity of mercury for heat is only = half that of water. But the capacities of bodies for heat are most conveniently referred to equal weights rather than measures; and if we thus compare water with mercury, it will be found that a pound of water absorbs thirty times more heat than the same weight of mercury; viewed, therefore, in this way, the capacity of water for heat is to that of mercury as 30 to 1, or as 1000 to 33, and we generally thus express the capacities of bodies for heat by a series of numbers, having this reference to water as = 1000, such numbers being their *specific heats*. Dulong and Petit have shown, as Dalton had previously anticipated, that the specific heat of bodies increases with their temperatures, so that it requires more heat to raise them a given number of degrees when they are at a high than when at a low temperature. The specific heat of iron, for instance, at different temperatures, was as follows:—

From 32° to 212°	0.1098
“ 32 to 392	0.1150
“ 32 to 572	0.1218
“ 32 to 662	0.1255

The same holds good in respect to other bodies, as shown in the following table:—

	Between 32° and 212°	Between 32° and 572°
Mercury	0.0330	0.0350
Zinc	0.0927	0.1015
Antimony	0.0507	0.0547
Silver	0.0557	0.0611
Copper	0.0949	0.1013
Platinum	0.0335	0.0355
Glass	0.1770	0.1900

Petit and Dulong's researches, however, render it probable that the *atoms* (or weights indicated by their equivalent numbers) of simple substances, all have the same capacities for heat; hence the specific heat of an elementary substance, multiplied into the weight of its prime equivalent, should always give the same product (*Ann. de Ch. et Phys.*, vol. x. 403).

This curious subject has lately been elaborately investigated by

Regnault, (*Ann. de Chim. et Phys.*, LXXIII. 1.) from whom I have abridged the following table, from which it will be observed that the products of his specific heats multiplied by their atomic weights do, in fact, only vary from about 38 to 42, hence the law of Dulong and Petit is verified, especially if allowance be made for errors in the determination of the specific heats, as well as in that of the equivalent numbers. The latter, in fact, are in some cases altered from those usually adopted, in order to adapt them to this law, which obviously furnishes an important test of their correctness. Most of the atomic weights in the table are the same as those employed by Berzelius, and agree upon the oxygen scale with ours upon the hydrogen scale; that, however, of silver, is only half, and that of uranium one-fourth, while the atomic weight of carbon is doubled: if the equivalent thus obtained for carbon be correct, carbonic acid, instead of being represented by $\text{Car.} + 2\text{O}$, would be $\text{Car.} + 4\text{O}$; the neutral carbonates as they now stand would thus become basic carbonates; and the bi-carbonates would stand as the neutral salts containing an atom of acid and an atom of base. Some of these considerations are important, as influencing our views of the atomic constitution of certain organic compounds.

	Specific Heat.	Atomic weight adopted by Regnault.	Product of the two.
Water	1.00		
Glass	0.19768		
Brass	0.09391		
Oil of Turpentine	0.42593		
Iron	0.11379	339.21	38.597
Zinc	0.09555	403.23	38.526
Copper	0.09515	395.70	37.849
Cadmium	0.05669	696.77	39.502
Silver	0.05701	675.80	38.527
Arsenic	0.08140	470.04	38.261
Lead	0.03140	1294.50	40.647
Bismuth	0.03084	1330.37	41.034
Antimony	0.05077	806.45	40.944
Tin	0.05623	735.29	41.345
Nickel	0.10863	369.68	40.160
Cobalt	0.10696	368.99	39.468
Platinum	0.03243	1233.50	39.993
Palladium	0.05927	665.90	39.468
Gold	0.03244	1243.01	40.328
Sulphur	0.20259	201.17	40.754
Selenium	0.0837	494.58	41.403
Tellurium	0.05155	801.76	41.549
Iodine	0.05412	789.75	42.703
Uranium	0.06190	677.84	41.960
Tungsten	0.03636	1183.00	43.002
Molybdenum	0.07218	598.52	43.163
Steel	0.11848	339.21	40.172
Charcoal	0.24111	152.88	36.873
Phosphorus	0.1887	196.14	37.024
Mercury	0.0332	1265.82	42.149

The specific heat of gaseous bodies has been examined by De La Roche and Berard (*Ann. de Chim.* LXXXV., or *Ann. of Philos.*, v. ii.); the following tables show their general results:—

	Equal volumes.	Equal weights.	Sp. gravity.
Air	1·0000	1·0000	1·0000
Hydrogen	0·9033	12·3401	0·0732
Carbonic acid . .	1·2583	0·8280	1·5196
Oxygen	0·9765	0·8848	1·1036
Nitrogen	1·0000	1·0318	0·9691
Nitrous oxide . .	1·3503	0·8878	1·5209
Olefiant gas . . .	1·5530	1·5763	0·9885
Carbonic oxide . .	1·0340	1·0804	0·9569

To reduce these numbers to the standard of water, three methods were employed; from which the numbers 0·2498, 0·2697, and 0·2813 were obtained for atmospheric air. They have taken 0·2669 as the mean, to which all the above results are referred, as follows:—

Water	1·0000	Nitrogen gas	0·2754
Air	0·2669	Nitrous oxide gas . .	0·2369
Hydrogen gas . . .	3·2936	Olefiant gas	0·4207
Carbonic acid gas .	0·2210	Carbonic oxide gas . .	0·2884
Oxygen gas	0·2361	Aqueous vapour . . .	0·8470

An extended table of specific heats may be consulted in Dr. THOMSON'S *Outline of the Sciences of Heat and Electricity*, 2nd edit.: but there can be little doubt that many of the hitherto received results are erroneous, as will be evident from the observations of Regnault, in the paper above quoted; and as he is pursuing his inquiries and extending them to gaseous bodies and to compounds, I have not thought it necessary to extend the above tables or to quote the inferences of De la Rive and Marcet (*Ann. de Ch. et Ph.*, xxxv. and xl.) or those of Avogadro and Neumann (*Ibid.* lv. and lvii.)

The capacity of bodies for heat is very materially affected by their *density*; whenever density is diminished, capacity for heat is increased, and *vice versâ*. Thus in regard to *solids*, if we suddenly compress a piece of metal, it becomes hot, because its capacity for heat is diminished; and, therefore, in its dense and compressed state, it contains less heat than it did before; this is seen in the process of coining, where the blank piece, in sustaining the sudden and violent pressure of the coining-press, becomes suddenly warm; and a piece of soft iron, upon being dexterously struck a few heavy blows with a hammer, becomes hot enough to inflame the sulphur of a match. A piece of Indian rubber, suddenly and forcibly drawn out, becomes warm in consequence of the extension, as may easily be perceived by applying it to the lip the moment it is stretched, that part being very susceptible of slight changes of temperature.

Similar changes of capacity for heat, attending change of density, are also perceived in *liquids*. When sulphuric acid is mixed with water, the relative density of the mixture is suddenly and greatly increased, and it becomes boiling hot. When alcohol and water are mixed, there is also an increase of density, and heat is evolved.

In *gases* we have a convenient opportunity of observing that, as on the one hand, condensation produces heat, so, on the other, rarefaction, or diminution of density, is attended by increased capacity for heat, or, in

other words, by the production of cold. Air, suddenly compressed by the piston of a syringe, evolves so much heat as to inflame combustibles exposed to it; but if we suspend a thermometer in the receiver of the air-pump, we shall find that, during exhaustion, the rarefaction or expansion which the air suffers, causes a diminution of several degrees of temperature; and this is one reason why the air in the higher regions is so much cooler than that below. As it ascends from the earth it expands; and in expanding, its capacity for heat is increased: it therefore cools itself, as well as the surrounding bodies. The Andes, placed almost under the line, rise in the midst of burning sands; about the middle height is a pleasant and mild climate; the summits are covered with unchanging snows; and these ranges of temperature are always distinct. The hot winds from below, if they ascend, become cooled in consequence of expansion; and the cold air, if by any force of the blast it is driven downwards, is condensed and rendered warmer as it descends.

When hot steam suddenly issues, under great pressure, from a small aperture into the atmosphere, its instantaneous expansion so far cools it, that, instead of scalding the hand held in it, as is the case with ordinary steam, it scarcely feels warm.

Another case in point is furnished by the Fountain of Hiero, as it is called, at Schemnitz, in Hungary. A part of the machinery for working these mines is a perpendicular column of water, 260 feet high, which presses upon a quantity of air enclosed in a tight reservoir: the air is consequently condensed to an enormous degree by this height of water, which is equal to between eight and nine atmospheres; and when a pipe communicating with this reservoir of condensed air is suddenly opened, it rushes out with extreme velocity, instantly expands, and in so doing it absorbs so much heat as to precipitate the moisture it contains in a shower of snow, which may readily be gathered on a hat held in the blast. The force of this is so great, that the workman who holds the hat is obliged to lean his back against the wall, to retain it in its position.

If the blast from an air-gun be directed upon a delicate thermometer, it sinks it a few degrees, from the cold produced by the sudden expansion of the air.

§ 8.—EFFECTS OF HEAT IN CHANGING THE FORM OF BODIES.

LATENT HEAT.

HAVING described the phenomena attendant upon the expansion of bodies by heat, and its propagation through liquids and gases by change of density, and through solids by their convective or conducting powers, we may now proceed to an important part of the history of this power of matter, namely, to *its effects upon the forms or states of bodies*.

When *solids* are exposed to a certain degree of heat, they change their state, and are converted into *liquids*; and *liquids*, under the same circumstances, are changed into *vapours* or *elastic fluids*: these again, by the loss of heat, revert to the liquid state; and liquids, by due degrees of cold, are solidified*. *Ice, water, and steam* are familiar instances of these

* It is probable that all substances are susceptible of these changes; though, on the one hand, the temperature required for the liquifaction and evaporation of

three states of matter, and the phenomena attendant on their production may be discussed under the heads *Liquifaction* and *Vaporization*.

§ 9.—LIQUIFACTION.

ONE important fact respecting the conversion of ice into water has already been mentioned, in describing the method of graduating thermometers (page 148), namely, that, during the progress of thawing, the ice and the water always maintain an uniform temperature, which is equal to 32° of Fahrenheit's scale. Suppose, for instance, that we bring some pounded ice from a very cold place (say of the temperature of 0°) into a room of the temperature of 60° , the ice, of course, soon begins to liquify, and a thermometer plunged into it rises from 0° to 32° ; but there it remains *stationary* until the whole of the ice has melted: the water thus formed, then gradually rises to 60° , which is the temperature of the surrounding air. Now it is obvious, that during the whole process of thawing under the circumstances above described, heat must be entering the ice, but its effect is, not to elevate its temperature, but to melt it: the heat apparently combines with the ice, to constitute water, but it does not affect the thermometer.

To heat thus united with bodies, Dr. Black gave the name of *latent* or *combined heat*; and he instituted a number of elegant experiments upon the subject of liquifaction and congelation, one or two of which may be here detailed: they are at once simple and satisfactory.

Two similar glass globes were filled, the one with five ounces of water, which was afterwards frozen, and the other with water cooled down to 33° . That which contained the ice was allowed to remain in a warmer air, till the ice began to melt, at which time its temperature was 32° . The two vessels were then suspended in the middle of a large room without a fire, or any notable draught of air, and of the temperature of 47° . The vessels, therefore, were under similar circumstances of temperature within and without, and with similar contents, except that the one contained *ice*, and the other *water*. The progress of heating was then noted. In that which held the water, the thermometer rose in *half an hour* to 40° ; but, in the other, it took no less than *ten hours and a half* before all the ice was melted, and the contents had reached 40° . Consequently, the rate of heating was *twenty-one times slower* in the ice-vessel than in that which held the cold water; but the actual heat received by the former was obviously nearly uniform the whole time; and, therefore, it required about twenty-one times as much heat to bring ice to the state of water, and to raise it to 40° , as to raise ice-cold water to the same point. Or, to express it by another form: if the water had continued to receive as great an influx of heat as the ice during the whole twenty-one half hours, its temperature would, of course, have been raised twenty-one times as much as during the single half hour; and, as this was 7° , the whole would have been twenty-one times 7° , or 147° . The difference between the gain of

some solids is extremely high; and on the other, the temperature required for the reduction of many gases to the liquid state unattainably low. Fusion is sometimes preceded by a softening of texture so as to admit of adhesion by *welding*, as in

porcelain, glass, iron, and platinum: and certain solids which are very volatile rise in vapour before fusion; in order to liquify them, they require to be heated under pressure.

temperature in the ice and the water, with equal accessions of heat, is therefore about 140° ; and thus 140° is the expression of that quantity of thermometric heat or temperature, which disappears, or is rendered latent by the separate operation of the liquifaction of ice; the actual quantities of matter in the comparison being equal. BLACK'S *Lectures*, and AIKIN'S *Dictionary*, Art. CALORIC.

The conclusions drawn from the preceding experiment on the *slow* thawing of ice, were verified and confirmed by melting it *rapidly* by mixture with hot water. Thus, if we take any quantity of finely-pounded ice, or of snow, at the temperature of 32° , and mix it with an equal weight of hot water, at the temperature of 172° , the snow melts, and the temperature of the resulting water is only 32° . Here, therefore, the water suddenly loses 140° of heat, while the temperature of the snow remains as at the outset of the experiment. So that 140° of heat have disappeared; they have combined with the snow; and their effect has been, *not to raise its thermometric temperature, but to convert it into water*. Ice, therefore, when it is converted into water, absorbs and combines with a certain proportion of *sensible* heat, and renders it *latent*. The exact number of thermometric degrees of heat which disappear during the liquifaction of ice have been somewhat differently estimated by different experimentalists. The mean of the whole is about 140° , which also is Dr. Black's inference.

From the preceding experiments we deduce this important general law—that in all cases of liquifaction, a quantity of heat not indicated by, or sensible to, the thermometer, is absorbed or disappears; and that this heat is withdrawn from the surrounding bodies, leaving them comparatively cold.

The cases which we have cited are those of liquifaction at comparatively low temperatures, and relate to ice and water; but the same laws are observed in all other cases, and where the temperatures are comparatively high: to these the term *fusion* is generally applied: spermaceti, for instance, fuses at 112° , and retains that temperature during its fusion, so long as any portion remains unmelted: when the whole is liquid, and not till then, its temperature may be elevated above the fusing-point. Again, a ladleful of lead cannot be heated red-hot till all the metal is melted; and a quantity of red-hot melted lead is instantly cooled down to its point of fusion (which is about 612°) by the addition of a piece of solid lead.

That the heat which becomes insensible, or latent, during the liquifaction of ice and other solids, *remains* in the liquid, and is not altogether lost or destroyed, is shown by the circumstance of its being again emitted, or given out, during their congelation. If a vessel of warm water be exposed in a very cold atmosphere, the temperature rapidly sinks to the freezing-point, and then it begins slowly to congeal: if kept in the same situation, heat is of course abstracted as before; but the thermometric heat remains stationary at about 32° , till the whole is frozen, after which the temperature of the ice begins again to sink.

Perhaps the result of this experiment is more explicitly stated as follows (THOMSON'S *Outline*, &c.):—If, when the thermometer is at 22° , we expose a vessel full of *water* at 52° to the open air, and beside it another vessel full of *brine*, at the same temperature, with thermometers in each, we shall find that both of them gradually lose heat, and are

cooled down to 32° . After this the brine (which does not freeze till cooled down to 4°) continues to cool without interruption, and gradually reaches 22° , the temperature of the air; but the pure water remains stationary at 32° : it freezes, indeed, but very slowly; and during the whole process its temperature is 32° . Now why should one liquid refuse, all of a sudden, to give out heat, and not the other? Is it not much more probable that the water, as it freezes, gradually gives out the heat which it had absorbed during its liquifaction, and that this evolution maintains the temperature of the water at 32° , notwithstanding what it parts with to the air during the whole process? It is easily shown that water, while congealing, is constantly imparting heat to the surrounding air; for a delicate thermometer suspended above it is constantly affected by an ascending stream of air less cold than the air around.

The following experiment also shows that this *evolution of heat* actually takes place *during congelation*. (Sir C. BLAGDEN, *Phil. Trans.*, 1798.) If, when the air is at 22° , we expose to it a covered glass of water, with a thermometer in it, the water, if kept quite still, may be gradually cooled down to 22° without freezing. It is, therefore, ten degrees below the freezing-point. If the water be now shaken, part of it instantly freezes, and the temperature of the whole rises to 32° ; so that the water acquires 10° of heat in an instant. Now, whence comes this heat? Is it not evident that it is derived from that part of the water which suddenly froze; and consequently, *that water, in the act of freezing, gives out heat?*

There are many instances of the sudden or rapid liquifaction of bodies, in which the absorption of heat, or production of cold, are more remarkable and striking than in the cases above detailed. When finely-powdered common salt, for instance, is mixed with pounded ice or snow, a *sudden liquifaction* of the solids ensues, and a proportionate *production of cold*; they immediately run down into brine, which does not freeze till reduced to near 0° ; and a thermometer plunged into the mixture sinks nearly to that point. We sometimes avail ourselves of this process, to remove hard trodden snow from the pavement in winter: it is soon liquified by sprinkling a little salt upon it, and the temperature of the air is seldom low enough to freeze the brine which is produced. Confectioners employ the mixture of ice and salt to freeze cream in the hot weather of summer; and the same system is conveniently resorted to whenever considerable cold is required. The production of cold by the liquifaction of metals, may be well shown by melting together 207 parts of lead, 118 of tin, and 284 of bismuth; these form on cooling a brittle alloy, which when reduced to powder and dissolved in 1617 parts of mercury at the temperature of 60° , produce a liquid amalgam the temperature of which falls to 14° .

In the case of the disappearance of heat caused by the sudden formation of *liquid brine* from its *solid* constituents, the bodies being already cooled to 32° , the thermometer sinks about 30° , or to 0° . It was once supposed that this was the lowest temperature that could be artificially commanded; and hence, probably, our thermometric scale sets out with it: but we now know that, by careful management, the mixture of certain materials will afford a much more intense cold. Among the

most effective of these is the mixture of snow and the salt called *chloride of calcium* or *muriate of lime*: the snow should be taken in its light flocculent state, as it falls in a very cold winter's day; and the chloride, in fine powder, but not deprived of all its water of crystallization, should be mixed with it in the proportion of about three parts to two: the mixture should be made in earthen vessels, previously cooled, and in the lowest atmospheric temperature we can command; the thermometer will then sink from 32° , to between 40° and 50° below 0° , a temperature at which mercury freezes. By the successive application of freezing mixtures in a proper apparatus, Mr. Walker succeeded in sinking the spirit-thermometer to -91° ; a temperature at which all liquids, with the exception of pure alcohol, are converted into the solid form. The following table shows some of the most useful of these freezing mixtures, and the temperatures which result from their careful application. (*Phil. Trans.*, 1795 and 1801.)

Mixtures.		Thermometer sinks.
	Parts.	
Muriate of ammonia	. 5	From 50° to 10° .
Nitre 5	
Water 16	
Nitrate of ammonia	. 1	From 50° to 4° .
Water 1	
Sulphate of soda 5	From 50° to 3° .
Diluted sulphuric acid 4	
Snow 1	From 32° to 0° .
Common salt 1	
Muriate of lime 3	From 32° to -50° .
Snow 2	
Snow 2	From -10° to -56° .
Diluted sulphuric acid 1	
Diluted nitric acid 1	
Snow or pounded ice 12	From 18° to -25° .
Common salt 5	
Nitrate of ammonia 5	
Snow 1	From -40° to -73° .
Muriate of lime 3	
Diluted sulphuric acid 10	From -68° to -91° .
Snow 8	

Whenever ice can be procured, its mixture with common salt furnishes the cheapest and most effectual freezing mixture; but when it cannot be obtained, we often conveniently avail ourselves of the two first saline combinations in the preceding table: either the mixture of hydrochlorate of ammonia and nitre, or of nitrate of ammonia and water, may be used, and the salts again be obtained by evaporation. In employing them to cool a bottle of champagne, for instance, a vessel should be selected a little larger, and nearly as tall as the bottle; it should then be filled with the coldest pump-water that can be procured, and the bottle placed in it: about four ounces of the salt in fine powder should be sprinkled upon the

shoulder of the bottle, so as, gradually dissolving, to fall or run down its sides; as the salt dissolves, the bottle should be gently turned in the mixture, and kept in it till an immersed thermometer tells us that the temperature is rising, which will be in about twenty minutes or half an hour. A table of the cold produced by dissolving sulphate of soda in dilute sulphuric acid, by Professor BISCHOF of Bonn, will be found in Dr. THOMSON'S *Outline of the Sciences of Heat and Electricity*. "A very convenient process for freezing a little water without the use of ice is to drench finely-powdered (crystals of) sulphate of soda with the undiluted hydrochloric acid of the shops. The salt dissolves to a greater extent in this acid than in water, and the temperature may sink from 50° to 0° . The vessel in which the mixture is made becomes covered with hoar-frost, and water in a tube immersed in the mixture is speedily frozen."—(GRAHAM.)

As liquifaction is to surrounding bodies a *cooling* process, and as sudden liquifaction produces sudden cold, so solidification or congelation is to surrounding substances a *heating* process; and when it takes place suddenly, a proportionably sudden elevation of temperature is the consequence. In the experiment described in page 111, a solution of Glauber's salt is made suddenly to crystallize; and if the hand be applied to the flask, it will be found to become sensibly warm. In this case the heat evolved is chiefly referable to the water, which solidifies and constitutes the water of crystallization of that portion of the salt which separates in crystals; when alcohol is added to a saturated solution of sulphate of potassa, the salt is precipitated in the solid form, and the mixture becomes warm. When water is poured upon quick-lime, a sudden solidification of a large portion of water is effected in consequence of its attraction for the lime, which crumbles down into a dry white powder, and a great evolution of heat ensues, as we see by the steam which makes its escape in the ordinary operation of slaking lime. When water is poured upon sulphate of copper or sulphate of magnesia, previously deprived by heat of their water of crystallization, much heat is evolved in consequence of their resuming it: in this case also the water suddenly passes from the liquid to the solid state.

From the view, then, which we have taken of the constitution of *liquids*, it is obvious that they *may be considered as combinations of solids with heat*; that, consequently, when they revert to the solid state, they give out their *heat of fluidity*, which, previously *latent*, or *insensible* to the thermometer, now becomes *sensible*, in consequence of the change of state: on the other hand, when solids are converted into liquids, they absorb or combine with that portion of heat which is requisite to their respective fluidities.

Thus, the *heat of fluidity* or *latent heat* of water is 140° , and that of the following substances in their liquid state has been determined by Irvine, namely, sulphur 144° , spermaceti 145° , lead 162° , wax 175° , zinc 493° , tin 500° , bismuth 550° .

We may conclude this part of our subject with the following table, by Dr. Ure, showing the freezing and melting points, as they are called, of different liquids and solids; that is, the temperatures at which the former congeal, and the latter liquify.

Sulphuric ether					-46°
Liquid ammonia					-46
Nitric acid, spec. grav.	1.424				-45.5
Sulphuric acid, spec. grav.	1.6415				-45

The solidifying temperature of the bodies above tallow, in the table, is usually called their *freezing* or *congealing point*; and of tallow and the bodies below it, the *fusing* or *melting point*.

The congealing points of the following metals are from Professor Daniell.

Mercury	- 39°	Zinc	773°
Potassium	+ 136	Silver	1873
Sodium	194	Copper	1996
Tin	442	Gold	2016
Bismuth	476	Cast Iron	2786
Lead	612	Pure Iron } above	3280
		Platinum }	

§ 10.—VAPORIZATION.

WE may now proceed to examine *the effects of heat upon liquids*. When liquids are heated, they are converted with more or less facility into invisible elastic fluids, or *vapours*. When water is heated in open vessels, its temperature gradually rises, and vapour is seen to form on its surface, which increases till the thermometer rises to about 212°, which is called the *boiling-point* of water: it is then violently agitated, and gradually disappears in the form of *steam*: but, although the source of heat is continued, the temperature of the water remains stationary, and both it, and the steam, continue at 212°. There are, therefore, in this simple operation, two leading circumstances to be attended to, namely, the degree of expansion which the water suffers by conversion into vapour; and the cause of that uniformity of temperature to which we have adverted, and which has been above noticed as furnishing one of the fixed points for thermometric graduation.

In regard to the *bulk* of steam formed by a given bulk of water, it appears, from the experiments of Gay Lussac, that a cubic foot of water is convertible into 1689 cubic feet of steam, at the temperature of 212° (the barometer standing at 29·9 inches). Mr. Watt conceived the bulk of steam to be about 1800 times that of the water; and others have far exceeded even Watt's estimate: we may, however, adopt that of Gay Lussac as the most accurate. Other liquids form different volumes of vapour; alcohol, for instance, gives 488 times its volume, ether about 212, and oil of turpentine 192, each at the temperature of 212°. It is obvious, therefore, that these vapours will differ materially in their respective densities. Steam is lighter than air, at the same temperature and pressure, in the proportion of about 10 to 16; the density of steam to that of air being as 625 to 1000. On the contrary, the vapours of alcohol, ether, and oil of turpentine are much heavier than air, the specific gravity of the first being 1·60, that of the second 2·58, and of the third 5·01, in reference to air as unity.

It has already been stated that the expansion of vapours by heat, and their contraction by cold, follows the same general law as that of gases, so long as the quantity of vapour continues the same; but if the vapour be in contact of the liquid producing it, then the increase of temperature will form a fresh portion of vapour, and the dilatation will proportionately exceed 1·480th of the whole bulk for each degree; so also will the contraction of a vapour on cooling deviate from the above law, whenever any portion reverts to the liquid state. Under varying pressure, the volume of vapour varies according to the same law as that of air, so long as the state of vapour is preserved.

Steam is an invisible elastic fluid like common air, and possessed of similar mechanical properties. We are, it is true, in the habit of associating a smoky appearance with steam, because we generally observe it when it is beginning to be condensed; as when it escapes, for instance, from the spout of a tea-kettle; but, when perfectly formed, it is quite invisible, as may be shown by boiling water in a flask, when perfect transparency will exist in the upper part of the vessel which is filled with the hot vapour; and it only becomes visible when it escapes into the air, and suffers incipient condensation.

The same general fact, in regard to the visibility of vapour, is shown by the production of *fogs*, which are occasioned by the mixture of warm with cold air; the general depression of temperature thus produced, rendering the aqueous vapour visible, in consequence of its partial condensation. This *partial* condensation does not amount to the actual precipitation of water, or *rain*; but consists of a multitude of thin *vesicles*; and hence the appearance is often called *vesicular vapour*: it constitutes clouds, mist, dew, and fogs. *Clouds*, therefore, are formed, whenever two masses of air, of different temperatures, and each saturated with moisture, meet and mix together; but what it is that subsequently causes the condensation of the vesicular vapour, and its precipitation in the form of rain, is not exactly known*.

Steam, as we have said, is produced by heating water to 212° under common barometrical pressure, the thermometer remaining fixed at that point, which is, therefore, called the *boiling-point* of water. *But this point, or temperature, varies with, and is immediately dependent upon, the pressure to which the surface of the water is exposed*; it is also, to a small extent, affected by the nature of the vessel containing the water. (GAY LUSSAC, *Ann de Chim. et Phys.*, vii., 307; *Quarterly Journal*, v., 361.) Thus in a glass flask the boiling-point of water often rises to 214° or 216° ; and where the steam is irregularly formed, occasioning a bumping in the vessel, the boiling-point is proportionately high and irregular, but upon throwing in a few metallic filings, pieces of wire, or other finely-divided and insoluble materials, the generation of steam is facilitated, and the boiling-point falls to its standard. Dr. Bostock has observed an analogous effect in ether and alcohol (*Ann. of Phil. N. S.*, ix., 196). Ether, heated in a glass vessel, had its boiling-point lowered many degrees by introducing a few shavings of cedar; and alcohol of the specific gravity of .849 had its boiling-point reduced in the same way

* "A mist or cloud consists not of solid drops, but of a multitude of very thin vesicles of water, similar to soap-bubbles. If clouds and fogs consisted of *drops*, their precipitation would be rapid; for a drop whose diameter amounted to a thousandth part of an inch would acquire a velocity of nine or ten feet per second: whereas we see clouds hover at a small elevation for hours; and they are transported from the sea, lake, river, or marsh, from which they are raised, far into the country, or to the tops of the mountains, where the requisite supply of

moisture cannot be had in any other way. Saussure, while travelling in the Alps, happened to be enveloped in a mist which was almost stagnant. He was astonished at the size of the drops, as he thought them, and at seeing them float slowly past him without falling to the ground. Some of them were larger than the largest peas. Catching them in his hand he found them to be bladders, inconceivably thin. Indeed, the optical phenomena exhibited by clouds and mists show that they are of a vesicular structure."—THOMSON.

between 30° and 40° . It is stated by Mr. Scrimgeour, of Glasgow, that if oil be present with water the boiling-point is always raised a few degrees.

The influence of fluctuations in the barometer upon the boiling-point of water is shown in the following table:—

Barometrical pressure, in inches, of mercury.	Temperature at which water boils.
27.74	208 $^{\circ}$
28.29	209
28.84	210
29.41	211
29.80	212
30.60	213

Of course, therefore, we find considerable *diminution* in the boiling-point of water upon the summits of hills and mountains, and other elevated situations; and a very delicate thermometer indicates a lowering of the boiling-point even at the top of high buildings. The Rev. Mr. Wollaston has described the method of constructing a thermometer of extreme delicacy, applicable to these purposes (*Phil. Trans.*, 1817). Saussure found that, at the top of Mont Blanc, water boiled at 187° . It appears from the above table that for every inch of variation in the barometer, the boiling-point of water varies 1.76 degrees; consequently, every tenth of an inch that the barometer rises or falls, either elevates or depresses the boiling-point by 0.176 of a degree; even the ordinary changes, therefore, in the height of the barometer will materially affect the boiling-point. In this country the *mean height* of the barometer is a little short of 30 inches: it very rarely rises higher than 31 inches, or falls below 28.5; so that from this cause alone, there will be a variation in the boiling-point of water of between four and five degrees.

The following table shows the boiling-points (at mean pressure) of several liquids, but the details upon this subject will be found under the separate heads of the substances themselves:—

Hydrochloric ether	52 $^{\circ}$
Sulphuric ether	96
Bisulphuret of carbon	116
Ammonia (sp. gr. 0.945)	140
Acetic ether	160
Alcohol (sp. gr. 0.798)	173
Water	212
Nitric acid (sp. gr. 1.42)	248
Crystallized chloride of calcium	302
Oil of turpentine	314
Naphtha	320
Phosphorus	544
Sulphuric acid (sp. gr. 1.84)	620
Whale oil	630
Mercury	662

The boiling-point of various saline solutions is partly dependent upon the quantity and partly upon the nature of the salt dissolved, and the steam arising from them has the same temperature as that of the boiling solution. (Faraday and Gay Lussac, *Ann. of Phil. N. S.*, v., 75.) Mr. T. Griffiths has determined the boiling-points of a number of saturated

solutions of salts, of which a table is given in the *Quarterly Journal*, xviii., 90. The following are a few of the results:—

Name of salt.	Dry salt in 100 of solution.	Boiling point.	Name of salt.	Dry salt in 100 of solution.	Boiling point.
Acetate of soda . . .	60 . .	256°	Alum	52 . .	220°
Nitrate of soda . . .	60 . .	246	Chlorate of potash .	40 . .	218
Nitrate of potassa . .	74 . .	238	Sulphate of copper .	45 . .	216
Muriate of ammonia .	50 . .	236	Sulphate of iron . .	54 . .	216
Muriate of soda . . .	30 . .	224	Acetate of lead . . .	42 . .	215
Sulphate of magnesia .	57 . .	222	Sulphate of soda . .	31 . .	213

If, as has already been remarked, *pressure* be diminished by artificial methods, the temperature at which liquids boil will be proportionately lowered; and hence we often use the terms *boiling* and *ebullition* to signify the rapid conversion of water into vapour, *independent of the temperature at which it takes place*: using the term in this sense, we shall presently have occasion to point out a case of boiling at the freezing temperature.

The air-pump is a very useful instrument for showing the influence of diminished pressure upon boiling-points. If, for instance, we place a glass of water of the temperature of 90° or 100° under the receiver of the air-pump, and remove the air's pressure upon it, we shall observe that the water soon boils violently at that temperature; and would continue so to do, but that the space in the receiver becomes filled with an atmosphere of aqueous vapour, which, exerting its pressure upon the water, again prevents ebullition.

If we use liquids which, under ordinary circumstances, boil at temperatures below that of water, we shall find them boiling in *vacuo* at proportionately low degrees; this is the case with *ether* and with *alcohol*, which, under the above circumstances, readily boil at all common temperatures.

It may here be observed, that we apply the term *vapour* to all elastic fluids which are easily reconvertible into liquids: *steam* is easily converted into *water* by lowering its temperature a few degrees; and those liquids which have low boiling-points are especially convenient for illustrating these changes; such, for instance, as ether or alcohol; and as ether is only sparingly soluble in, and much lighter than water, it may be used in the following illustrative experiment. Nearly fill a glass tube about three feet long, and half an inch diameter, with water; then pour a little ether upon the surface of the water, and closing the open end of the tube carefully with the palm of the hand, invert it in a basin of water, as shown in fig. 75: the ether will rise through the water, and occupy the upper end of the tube, *a*, retaining, at common temperatures, its liquid state; but if we now pour a little hot water upon, or hold a heated iron near, the exterior of the tube, it presently causes the ether within to boil, and its vapour

may thus be made to drive nearly the whole of the water out of the tube into the basin below: the ether retains this elastic or vaporous state, so long as its temperature is sufficiently high; that is, above 100° ; but if we now cool the tube, by suffering some cold water to dribble over it, the ethereal vapour returns to its liquid state, and floats upon the water as before. At temperatures above 212° , water would be in the same predicament as ether.

With regard to the bodies usually called *gases*, they are not thus easily condensable: a few of them become liquids when considerably cooled, and several others when subjected to great pressure; but at ordinary temperatures and pressures the gases are permanently elastic.

The following apparently paradoxical experiment illustrates the influence of diminished pressure in facilitating ebullition.

76

Insert a stop-cock securely into the neck of a Florence flask containing a little water, and heat it over a lamp till the water boils, and the steam escapes freely through the open stop-cock; then suddenly remove the lamp and close the cock; the water soon ceases to boil; but if the flask be now plunged into a vessel of cold water, as represented in fig. 76, ebullition instantly recommences, but it again ceases on holding the flask near the fire, or over the lamp. In this experiment

the air is driven out of the flask, and an atmosphere of steam included within it, which, upon immersion in cold water, is condensed, and a vacuum formed above the water, which, upon the principle already noticed, boils under the diminished pressure: the vacuum is kept up by the successive condensations of the portions of steam formed; but if the flask be removed from the cold medium, and especially if it be warmed, a new atmosphere of steam is formed, the pressure of which prevents ebullition.

Boiling in a more or less perfect vacuum is sometimes resorted to upon a large scale in the arts; and it has been successfully applied to the refining of sugar, the syrup being thus concentrated to the granulating point, without the risk of decomposing it. The same plan has been resorted to in the Pharmaceutical Laboratory, in the preparation of certain medicinal substances, the properties of which are easily impaired by heat. Mr. Barry has described a simple and effective apparatus for these purposes, in the *Medico-Chirurgical Transactions* (vol. x).

If we reverse the state of things just explained, and expose liquids to increased pressure, we proportionately elevate their boiling-points. Papin contrived an instrument for this purpose, which was called a *digestor*. It was a cylindrical copper vessel, having a lid very nicely fitted to it and secured by screws. If such a vessel be about half filled with water, with the lid closely secured, and then put upon the fire, steam is soon formed; but having no escape, it presses upon the water, and prevents the further formation of steam till the temperature of the water rises above the boiling-point. This heat being conveyed to the steam, it now receives

another portion of vapour without being condensed, and thus the *quantity* and *elasticity* of the steam are continually increasing with the temperature. Water has in this way been raised to the temperature of 419° , or even above it; for Muschenbroek asserts that he raised the temperature of the water high enough to melt tin, which requires a temperature of 440° . The powerful effects of high-pressure steam are illustrated upon a small scale by the little glass bubbles commonly called *candle or fire-crackers*; they are hermetically sealed, and contain a drop of water, which occasions them to burst with great violence, when sufficiently heated. But in speaking of the elastic force of steam it must be recollected that it does not in itself possess greater elasticity than air, so that vessels filled with steam only and containing no water in its liquid state, may be heated to any degree without more risk than if they only contained air.

The annexed is a good form of apparatus for illustrating, within certain limits, the influence of pressure upon the temperature of steam:—*a*, fig. 77, is a strong brass globe, composed of two hemispheres screwed together with flanches; a portion of quicksilver is introduced into it, and it is then about half filled with water: *b* is a barometer-tube passing through a steam-tight collar, and dipping into the quicksilver at the bottom of the globe: *c* is a thermometer graduated to about 400° , and also passing through an air-tight collar: *d* is a stop-cock, and *e* a large spirit-lamp. The whole is supported upon the brass frame and stand *f*. Upon applying heat to this vessel, the stop-cock being closed as soon as the water boils, it will be found that the temperature both of the water and of its vapour increases with the pressure, the extent of which is measured by the ascent of the mercury in the barometer-tube.

According to Southern, the temperature of steam under a pressure of two atmospheres is 250° , under that of four, 293° , and under that of eight, 344° . The results obtained by Dulong and Arago in reference to this question, are contained in the following table: they were obtained by experiment up to a pressure of twenty-five atmospheres, and at higher pressures by calculation. (*Quarterly Journal*, N. S. vii, p. 119.) See also Dr. Ure's table, *Phil. Trans.*, 1818.

The temperature of steam is always the same as that of the liquid producing it; hence the high temperature of steam generated under pressure: and as this elevation of temperature may be accurately regulated by the degree of pressure, *high-pressure steam* is often conveniently applied as a source of steady heat.

We are now to show, more particularly, that the production of vapour is in all cases attended by loss of sensible heat; and that, as in the case of *liquefaction*, heat disappears, to constitute the liquid, so, in all cases of *evaporation*, heat becomes, to a much greater extent, latent in the vapour.

The fact already adverted to, that we cannot, under ordinary circumstances, raise the temperature of water above 212°, although heat continues as before to flow into it, shows that the heat must be latent in the steam, the temperature of which does not exceed that of the water which produces it; and again, when water, as in the preceding experiment with the brass globe, is heated under pressure to a temperature above its ordinary boiling-point, the moment that that pressure is removed by suddenly opening the cock, a quantity of steam rushes out, and the remaining water has its temperature lowered to 212°. The quantity of water in this case, which constitutes the lost steam, is very small, yet it carries off the whole excess of heat from that remaining in the globe.

Dr. Black instituted some ingenious and simple experiments to determine the actual loss of heat during the conversion of water into steam. (BLACK'S *Lectures* and AIKIN'S *Dictionary*.) He heated water in a tin vessel up to its boiling-point, and noted the time required for the purpose. The same heat was then continued till the whole of the water was evaporated; and the time taken up by that process was also noted. Now, since, on the one hand, the accession of heat was constant, it was easily computed how high the temperature would have been, supposing the rise to have gone on above 212°, in the same ratio as below it; and, on the other, as the temperature of the steam was not raised, it was inferred that all the accession of heat from 212° was essential to the very state and constitution of steam at that temperature; this quantity was estimated at about 810°; that is to say, that the same quantity of heat which is required totally to evaporate boiling water at 212°, would be

sufficient to raise the water 810° above the boiling-point, or to 1022° , if it had remained in the *liquid* state. Dr. Ure estimates the *latent heat* of steam at 1000° , and has given the following as the latent heats of other vapours.

Vapour of alcohol	457°	Vapour of nitric acid	550°
" ether	312	" liquid ammonia	866
" oil of turpentine	184	" vinegar	903

On the other hand, when steam is again condensed into water, it necessarily gives out the latent heat which was essential to its state of vapour, and which, being then set *free*, will raise the temperature of adjacent bodies as much more than an equal weight of boiling water would do, as the latent heat of the steam exceeds the sensible heat of the water*.

The small boiler, represented in fig. 78 may be conveniently employed in these experiments on the latent heat of steam. (HENRY'S *Elem. Chem.*)

For this purpose the tube *e* must be screwed on the stop-cock *b*, and immersed into the glass of water *f*. The cock *c* being closed, the steam arising from the boiling water *a*, will pass into the cold water *f*, the temperature of which will be much augmented by its condensation. Ascertain the increase of temperature and of weight, and the result will show how much a given weight of water has had its

temperature raised by a certain weight of condensed steam. To another quantity of water, of the same weight and temperature as that in the jar at the outset of the experiment, add a quantity of water at 212° , equal in weight to the condensed steam; it will be found, on comparing the resulting temperatures, that a given weight of steam has produced, by its condensation, a much greater elevation of temperature than the same quantity of boiling water. If, for instance, 100 gallons of water at 50° be mixed with 1 gallon at 212° , the temperature of the whole will be raised by about 1.5° . But, if a gallon of water be condensed from the

* It has sometimes been supposed from the low latent as well as sensible heat of the vapours of alcohol and ether, that they might be economically substituted for steam as sources of mechanical power, but as the cost in fuel would be

proportionate to the latent heat of equal volumes of their respective vapours it will be obvious from the following statement that if alcohol and ether could be procured as cheap as water, the latter would be most economical.

1 cubic foot of	Cubic feet of vapor.	Latent heat of equal volumes.
Water	= 1689	1000
Alcohol	= 488 : 457 :: 1689	1550
Ether	= 212 : 312 :: 1689	2500

state of *steam* in a still-tub containing 100 gallons of water, the water will in that case be raised 11° . A gallon of water, therefore, condensed from steam, raises the temperature of 100 gallons of cold water 9.5° more than the addition of a gallon of boiling water: consequently, if the heat imparted to 100 gallons of water by 10 pounds of steam could be condensed in 1 gallon of water, it would raise it to 950° ; and a gallon of water converted into steam of ordinary density, contains as much heat as would bring five and a half gallons of ice-cold water to the boiling-point. The quantity of ice which is melted by steam of mean density is seven and a half times the weight of the steam.

In breweries and other manufactories where large quantities of hot water are consumed, it is frequently heated by conveying steam into it, or by suffering steam pipes to traverse the vessels, or by employing double vessels. This method of warming water has also been advantageously applied to heating baths. Where a higher temperature than 212° is required, it is necessary to employ steam under adequate pressure. The heat given off by steam during its condensation, is also often applied to warming air, and is at once safe, salubrious, and economical.

Whatever may be the *density* of steam, the same weight contains the same quantity of heat, so that distillation or evaporation at low temperatures is not attended by any saving of fuel; the latent heat is increased in proportion as the sensible heat is diminished. (SHARPE, *Manchester Memoirs*, 2nd series, ii.) Mr. Daniell illustrates this principle as follows. "Let us imagine that in a cylinder furnished with a piston we have a certain quantity of steam, and that it is suddenly compressed by a stroke of the piston into half its bulk without being reduced to the liquid state: it would acquire double elasticity, and its temperature would be increased. If we either suppose the cylinder incapable of transmitting heat, or take the moment instantly following the compression, before any heat has had time to escape, it must be evident that the sensible and latent heat together before the compression are precisely equal to the sensible and latent heat after the compression; but in the dense steam the sensible heat is increased and the latent heat diminished by equal quantities. Reversing this imaginary experiment, if we suppose only half the cylinder to contain steam at 212° , and the piston to be suddenly raised so as to double its volume, the density will of course be reduced to half, and its temperature will fall, but its sensible and latent heat together will remain unchanged." Mr. Daniell quotes the following results of Clement and Desormes in reference to this subject.

A certain weight of steam at 212° condensed at 32° , gives out	}	180° sensible heat.
		950 latent heat.

The existence of vapours of great density under high pressures and temperatures has been shown by the experiments of M. Cagniard de la Tour. (*Ann. de Ch. et Phys.*, xxi. 127—178; *Quarterly Journal*, xv. 145.) Although pressure restrains the volatilization of a liquid, it occurred to him that there should be a limit beyond which liquids would notwithstanding be converted into vapour, provided sufficient space be allowed for its generation. A strong glass tube, two-fifths filled with alcohol, and hermetically sealed, was slowly and carefully heated; as the fluid dilated, its mobility increased, and when its volume was nearly doubled, it suddenly disappeared, and became a transparent vapour. The same results were obtained with naphtha and ether; the latter requiring less space than the former to be converted into vapour without breaking the tube, and naphtha less space than alcohol. The presence of atmospheric air in the tubes did not interfere with the results. The same experiment succeeded, though difficultly, with water, the tube containing only about one-fourth its volume. M. Cagniard de la Tour ascertained, by means of a mercurial gage, the pressures of the above vapours. Alcohol, occupying in vapour a space little more than thrice its liquid volume, exerted a pressure = 119 atmospheres, and required for its production a temperature = 405° . Ether, under the same circumstances, exerted a pressure of 38 atmospheres at 320° . The temperature of the dense vapour of water was nearly that of melting zinc.

The same general laws which preside over the formation of steam at *high* temperatures influence its production at *low* temperatures: the constitution of vapour, therefore, is always the same. When water slowly evaporates under exposure to air, its vapour mixes with the surrounding atmosphere, and the process is usually called *spontaneous evaporation*; it takes place at all temperatures, and with a rapidity proportionate to the dryness of the air, and the velocity of the current passing over it: thus, in manufactories, where large quantities of liquids are to be evaporated, instead of heating them in the usual way, a current of hot air is made to pass over the surface of the fluid.

As, therefore, vapour slowly formed in cases of spontaneous evaporation, is similarly constituted to that produced by rapid ebullition, there being the same loss of *sensible heat* in the one case as in the other, it follows that the exhalation of humidity which is almost constantly going on from the earth's surface, must powerfully modify natural temperatures, and prevent accumulation of heat; the vapour forms mists and clouds, and when these are condensed into rain, their latent heat is again given out in the upper and cold regions. The conversion, therefore, of water into vapour, and the condensation of vapour in the form of dew and rain, is a process of the utmost importance, and tends considerably to the equalization of temperature over the globe. Dalton has shown that the actual quantity of vapour which can exist in any given space, entirely depends upon temperature. Thus, if some water be put into a dry flask, at 32° , very little vapour will be formed; it will contain more at 50° , and yet more at 70° . But if, being at 70° , the temperature be lowered to 32° , vapour will be condensed, and the portion retained will not exceed that originally taken up at 32° . The actual result of these experiments is the same when the flask is empty as when it contains air, but in the former case the evapora-

tion is most rapid, for the air affords some mechanical resistance to the distribution of the vapour.

The following table shows the elastic force and the weight of aqueous vapour at different temperatures:

Temp.	Tension in inches of Mercury.	Weight of a cubic foot.
32°	0·216	2·53 grains.
40	0·280	3·23
50	0·400	4·53
60	0·560	6·22
70	0·770	8·39
80	1·060	11·33
90	1·430	15·00
212	30·000	257·22

The relative volatility of bodies and the elastic force of their respective vapours may be estimated by their effects upon the column of mercury in the barometer tube. Thus, if we range five barometers side by side, one of which may serve as a standard, and then throw up a little water into

the second, alcohol into the third, ether into the fourth, and sulphuret of carbon into the fifth, each column will be depressed in proportion to the elastic force of the respective vapours. If the whole space above the mercury in each tube be equally heated, the increase of tension with increase of temperature may be measured; but if the liquids only be heated, the tension will not increase, because the respective vapours will be condensed as soon as formed. 1, represents the standard barometer; 2, the depression by the vapour of water; 3, by alcohol; 4, by ether, and 5, by sulphuret of carbon.

When liquids are exposed to the atmosphere, evaporation is proportionate to the surface exposed, and is therefore greatly accelerated by increasing the surface, as by exposing them in very shallow vessels, or suffering them to trickle over solid bodies; it is also accelerated by agitating the superincumbent air, as in the case of a brisk wind, or by artificial means: when the air is tranquil, the vapour

rests upon the surface of the water, and it is the pressure of its own vapour on the surface of a liquid, and not that of the gaseous atmosphere, which stops the process. The following table, drawn up by Mr. Daniell from the experiments of Dr. Dalton, shows the force of vapour at different temperatures, and the rate of evaporation per minute from a circular sur-

face six inches diameter; the amounts of evaporation refer to dry air; if vapour be already present, as it always is in our atmosphere, the quantity of evaporation at any given temperature will be the quantity indicated in the table, *minus* the quantity already incumbent upon the water. (DANIELL, § 196.)

Temp.	Force in inches of Mercury.	Calm. grs.	Breeze.	High Wind.
212°	30·000 . . .	120·00 . . .	154·00 . . .	189·00
85	1·235 . . .	4·92 . . .	6·49 . . .	8·04
75	0·906 . . .	3·65 . . .	4·68 . . .	5·72
65	0·657 . . .	2·62 . . .	3·37 . . .	4·12
55	0·476 . . .	1·90 . . .	2·43 . . .	2·98
45	0·340 . . .	1·36 . . .	1·75 . . .	2·13
35	0·240 . . .	0·95 . . .	1·22 . . .	1·49
25	0·170 . . .	0·67 . . .	0·86 . . .	1·05

By inducing rapid evaporation, at common or low temperatures, we have it obviously in our power to produce considerable degrees of cold. If a wet cloth is spread out in a keen wind at a temperature a few degrees above freezing, the water, by its rapid evaporation, soon carries off so much heat as to freeze the remainder, making the cloth hard and stiff by the formation of ice within its pores.

There is no liquid better calculated for making experiments on the cold produced by spontaneous evaporation, than *sulphuric ether*; it is extremely vaporisable at ordinary temperatures, and if we pour a little of it into the palm of the hand, and blow gently upon its surface, we observe that, as it disappears in vapour, a very sensible degree of cold is produced.

If we fold a strip of cambric round the bulb of a small thermometer and suffer ether to dribble over it from a dropping-bottle, at the same time accelerating the evaporation by blowing gently upon it with the mouth or a pair of bellows, we shall observe the mercury fall to several degrees below the freezing-point; and if we substitute for the thermometer a thin glass tube, containing a small quantity of cold water, a little dexterous management will enable us by the same means to freeze it.

This congelation of water by the evaporation of ether, furnishes, by the help of the air-pump, a very striking experiment. Provide a small thin glass flask, which fits tolerably close into a bell-shaped wine-glass, as represented by the annexed cut (fig. 80). Pour a little good ether into the flask, and some cold water into the wine-glass, so that each may stand at about the level *a*, and place the whole apparatus, thus arranged, under the receiver of an air-pump. During exhaustion, the ether will *boil*, that is, it will very rapidly pass off in the state of vapour. Now, the vapour of ether, like all others, requires *heat* for its formation, and this it takes from the surrounding bodies, and, among the rest, from the adjacent water, which soon *freezes* in consequence of the loss of that portion of heat which was essential to its fluidity, but which has been carried away and pumped out in the

ethereal vapour. It sometimes happens that the success of this experiment is prevented by the ether boiling over into the water, and so preventing its congelation; but this may be guarded against by putting a little bit of wood or paper into the ether, which causes it to boil regularly, and prevents sudden jets of vapour.

There is an experiment yet more illustrative of the absorption and disappearance of sensible heat during evaporation, which consists in freezing water by causing it rapidly to evaporate at low temperatures; it

is performed as follows: upon the plate of a good air-pump place a flat shallow glass dish, A, about half-filled with sulphuric acid, and a little above it a tin or copper basin, B, three parts filled with water, with a small thermometer, c, immersed in it (fig. 81). This basin, which should be of the shape shown in the cut, may be conveniently

supported upon three glass legs, D, standing in the acid. Over the whole, place an air pump receiver, not larger than requisite, and proceed to withdraw the air. We first observe the escape of air from the water; the thermometer gradually sinks; the water then, in consequence of the rapidity of its evaporation, appears to boil; and if the whole apparatus is in good order, it freezes in the course of five or ten minutes. The use of the sulphuric acid is to absorb the aqueous vapour, which it does very energetically, and consequently occasions a constant fresh call upon the water for its formation. Now we have shown that *vapour cannot be produced without the absorption of heat*; and, in the case before us, the heat requisite to convert *one* part of the water into *vapour* is taken from the *other fluid portion*, which, thus losing the heat that constituted its fluidity, becomes solid, or freezes. There is another phenomenon often observable in this experiment, which is, that the temperature of the water falls several degrees below the freezing-point, before congelation takes place; but the moment that it freezes, it rises to 32° , in consequence of the escape of the residuary latent heat. Leslie, who contrived this process, proposed it as a means of procuring ice in hot climates, and suggested for the purpose, a large single air-pump, capable of exhausting six or eight receivers at a time. He has also shown, that parched oatmeal, and certain dried earthy substances, may be substituted, as absorbents, for the sulphuric acid; but they are far less effectual.

Dr. Wollaston's *cryophorus*, or ice-bearer, illustrates the same general facts, in a more simple manner than the preceding; it depends upon the same common principle, but the vacuum and the evaporation are brought about in a different way. It is a tube, having a bulb at each extremity, one of which is half filled with water, as represented in fig. 82; the interior of

the tube is perfectly deprived of air, by boiling the water in one of the bulbs till a jet of pure steam issues through a small opening left at the

bottom of the other, which is then sealed by fusion in the flame of a lamp the consequence is, that the water in the other bulb is greatly disposed to evaporate; but this evaporation can only proceed to a certain extent, because the pressure of vapour within the tube soon prevents its further progress. To get rid of this, to keep up the vacuum, and to occasion a constant demand upon the water for the fresh formation of vapour, the empty ball is plunged into a freezing mixture, which continually condenses the vapour within, and so accelerates the evaporation of the water in the other bulb, as to cause it ultimately to freeze. The success of this experiment, when it is attempted in a warm room, where there are several persons, is often frustrated by the rapid deposition of moisture, arising from the condensation of ærial vapour upon the water-bulb; an effect which may be prevented by protecting it from the free access of fresh portions of air, by immersion in a covered glass, as shown in the following sketch, fig. 83, which also represents the empty bulb surrounded by a freezing mixture of pounded ice and salt. The intermediate tube between the bulbs of the cryophorus may be of any length: about two feet is most convenient, for when longer it is very apt to be broken.

There are many cases in which we resort to accelerated evaporation, at common temperatures, as a source of cold, without, however, carrying it so far as to produce ice. The sprinkling of floors and pavements with water tends to cool them and the air, by its evaporation at summer temperatures: *wine-coolers* are porous earthen vessels, which are dipped into water, and, during exposure to air, become cooled by its escape from their surfaces in the form of vapour; and in some hot climates, porous bottles are filled with water, and suspended in a current of air; the water oozes to the surface, whence it is rapidly removed by evaporation, and cold is consequently produced.

It will be obvious, from the facts now adduced, that all *vapours* may be considered as combinations of solids or liquids with heat, and Mr.

Faraday's discoveries sanction us in regarding *gases* as similarly constituted; some of these are condensible by *cold*, others by *pressure*, into the liquid state: and we thus learn that they are merely the vapours of extremely volatile liquids, the boiling-points of which, under common atmospheric pressure, are, in many instances, lower than any natural temperatures. Under great pressure these gases may be coerced into the liquid state, and, upon its removal, they instantly reassume the gaseous form, some with explosion, and some with the appearance of brisk ebullition, and the production of intense cold.

Mr. Faraday condensed the gases by exposing them to the pressure of their own atmospheres. He put the materials for producing them into a strong glass tube, a little bent in the middle, and hermetically sealed. When necessary, heat was applied, and when the pressure within became sufficient, the liquid made its appearance in the empty end of the tube, which was artificially cooled to assist in the condensation. In these experiments much danger is incurred from the bursting of the tubes: so that the operator should protect his face by a mask, and his hands by thick gloves. He succeeded in liquifying the following gases, which, as will be seen, require various degrees of pressure for the purpose.

	Pressure in Atmospheres.	Fahr.		Pressure in Atmospheres.	Fahr.
Sulphurous acid	2	at 45°	Sulphuretted hydrogen	17	at 50°

§ 11.—THEORY OF THE STEAM-ENGINE.

So many of the phenomena attendant on evaporation and liquifaction are illustrated by the action and principles of the *steam-engine*, that it may be worth while to refer to the construction and operation of that machine, as elucidating several points already adverted to.

The action of the steam-engine depends principally upon the two leading properties of steam which have been dwelt upon—namely, *its expansive force*, and *its easy condensation*. To take the most simple view of these as moving powers, let *a*, fig 84, represent a glass tube with a bulb at its lower end. It is held by a ring and handle *b*, and contains a piston *c*, which, as well as its rod, is perforated, and may be opened or closed by the screw at top *d*: it is kept central by passing through a slice of cork at *e*. When used, a little water is poured into the bulb, and carefully heated over a spirit-lamp; the aperture in the piston-rod being open, the air is thus expelled, and when steam freely follows it, the screw may be closed, when, on applying cold to the bulb, the included steam is condensed, and a vacuum formed, which causes the descent of the piston, in consequence of the air pressing upon it from above. On again holding the bulb over the lamp, steam is reproduced, and the piston again

forced up; and these alternate motions may be repeatedly performed by the alternate applications of heat and cold. This instrument gives a tolerably correct notion of the application of steam in the old engines, where it was employed conjointly with the air's pressure as a moving power.

In the most perfect construction of Watt's engine, steam is exclusively employed both for elevating and depressing the piston; and the following diagrams and description may perhaps enable the reader to understand the very ingenious method in which it is thus applied:—(See figs. 85 and 86.)

a is the *steam-pipe* issuing from the boiler, and so contrived as alternately to deliver steam into the *cylinder b*, above and below the piston *c*.

b is the main *cylinder* of the engine.

c is the *piston*, with the *piston-rod* passing through an air-tight collar at the top of the cylinder, which is commonly called the *stuffing-box*.

d is the *eduction-pipe*, by which the steam, having performed its duty in the cylinder, makes its escape into the *condenser*.

e is the *condenser*, immersed up to the level *g*, in a cistern of cold water.

f, the *injection-cock*, by which a small jet of cold water is admitted into the condenser.

h, a pipe communicating with a pump called the *air-pump*, by which the condensed steam and injection-water are continually pumped out of the condenser: it also pumps out the air, and keeps a constant vacuum in the cylinder and condenser.

i represents the moveable plug of a cock which has two passages, and which opens alternate communications with the steam-pipe and the eduction-pipe. In fig. 1, this plug is shown in the position which admits the steam to pass into the cylinder *above* the piston: in fig. 2, the plug has shifted its position, and now admits the steam to pass into the cylinder *below* the piston: in the former case the condenser is open to the space below the piston; in the latter, to the space above the piston.

Let us now suppose a vacuum to exist in the cylinder *b*; the steam passes through the pipe *a*, in the direction of the arrows (fig. 85), and entering the cylinder *above* the piston, immediately forces it *downwards*. The piston having reached the bottom of the cylinder, the plug of the cock *i* shifts its position, and is now as represented in fig. 86; the steam enters as before at *a*, and passes in the direction of the arrows to the *bottom* cylinder, so as to *elevate* the piston. It is obvious that this action could not take place unless the steam, by which it had previously been depressed, were removed; this therefore makes its escape by the *eduction-pipe d*, (fig. 86), and passes into the *condenser e*, where it reverts to the state of water, which is got rid of by the *air-pump* through the pipe *h* (fig. 85). The piston being now in the position represented in fig. 85, and the plug having again shifted its position, the steam enters *above* the piston as before, while the space *under* the piston has now a free communication with the condenser by the eduction-pipe *d*; so that the steam, which had first been active in raising the piston, is not in the way of its depression. I have here represented and described what may, perhaps, be called the simplest form of this engine, in order to render its *principle* as intelligible as diagrams admit. Instead of the four-way plug *i*, sliders or sliding-valves are generally used, as being less liable to wear, and more easily kept airtight; but in all cases the same alternate communication with the boiler and with the condenser is effected.

§ 12.—RADIANT MATTER. REFLECTION AND REFRACTION OF LIGHT.

OF the substances belonging to our globe, some are of so subtle a nature as to require minute and delicate investigation to demonstrate their existence; they can neither be confined nor submitted to the usual modes of examination, and are known only in their states of motion, as acting upon our senses, or as producing certain changes in the more gross forms of matter. They have been included under the general term of **RADIANT, IMPONDERABLE, or ETHEREAL MATTER**, which, as it produces different phenomena, must be considered as differing either in its nature or affections. Respecting the nature of these phenomena, two opinions have been entertained, and each ably supported. It has been supposed by Huygens, Euler, and Descartes, that they arise from vibrations of a rare elastic medium which fills space; while Newton has considered them as resulting from emanations of particles of matter. The former opinion has been ably advocated by Dr. Young, who has selected from Newton many passages favourable to the undulatory theory, and has shown that it explains phenomena not easily consistent with the theory of radiating particles. (Young's *Nat. Phil.*, ii., 631. See also Fresnel's *Exposition of the Undulatory Theory* in the first volumes of the *Quarterly Journal*, *N.S.*)

It may suffice here merely to advert to these opinions, without touching upon the reasoning by which they are respectively supported, and which has no immediate connexion with chemical science: there are, however, certain affections and effects of light, and of the heat that radiates from the sun, and from terrestrial bodies, which form an important part of chemical philosophy, and constitute one of the principal links by which it is connected with physical inquiries.

The phenomena of vision are produced either by bodies inherently luminous, such as the sun, the fixed stars, and incandescent substances; or they are referable to the reflection of light from the surfaces of bodies. It is thus that the objects around us are visible by reflecting the sun's rays in the day-time, but become lost in obscurity when that luminary sinks beneath the horizon. The manner in which the eye is affected by luminous bodies, shows that light is transmitted in *right lines*, and every right line drawn from a luminous body to the eye is termed a *ray of light*; and, as a congeries of rays possesses the same properties as the single ray, the same abstract term is frequently employed to designate the congeries, which is also called a *pencil* of rays.

The discoveries of Roemer, (*Phil. Trans.*, vol. xii.,) and of Bradley, (*Phil. Trans.*, vol. xxxv. and xlv.,) have shown that *the motion of light is progressive*, and that it is about eight minutes and thirteen seconds in passing from the sun to the earth, so that it may be considered as moving at the rate of 192,000 miles in a second; and, in the language of Herschel, (*Discourse on the Study of Natural Philosophy*, p. 23,) it performs the tour of the world "in about the same time that it requires to wink with our eyelids, and in much less than a swift runner occupies in taking a single stride." It is with extreme difficulty that we can conceive either emanations of matter or ethereal undulations to assume such extreme velocity, for, in the former case, how inconceivably minute must particles be, not only to impinge without injury upon terrestrial objects, but even to fall without pain upon our delicate sensual organs; and in the latter, how subtle and attenuated must be the medium by or through which the vibratory impulses are communicated.

We get some notion of *the velocity of light* by comparing it with the progress of *sound*, which moves at the rate of about 1000 feet in a second, or 760 miles in an hour; yet, its comparatively tardy progress is recognised, in observing the time that elapses between the flash and the report of a gun fired at a distance; the latter reaching the ear some time after the former comes to the eye; a period of nearly five seconds elapses when the gun is only a mile off, and we are thus enabled with some degree of accuracy to calculate the distance of luminous phenomena attended by sound; the varying time that elapses between seeing a flash of lightning and hearing the thunder is another familiar instance, and from it we infer the distance and course of the electric discharge.

Although, therefore, the sun is so far distant from the earth, that a cannon-ball, proceeding with its greatest speed, would be twenty years in reaching it*, and, that although almost a million times larger than the earth, its magnitude, as viewed from the earth, scarcely exceeds that of the moon, which is not much more than one-fourth the diameter of our globe, (the former 2160; the latter 8400 miles; the diameter of the sun being 882,000 miles,) yet, such is the velocity of light, that a flash of it from that luminary would be seen in little more than eight minutes after

* "The earth, moving at the rate of nineteen miles in a second, would take two months to pass through a distance which a ray of light would dart over in eight minutes. The subsequent discovery of the aberration of light confirmed this astonishing result."—MRS. SOMERVILLE.

its emission; whereas, the sound evolved at the same time (supposing a medium like air capable of conveying sound between the sun and the earth, and the distance 95 millions of miles) would not reach us in less than 14 years and 87 days. It is evident, therefore, that certain astronomical phenomena are not visible upon the earth, till a certain time after their occurrence; and it was this observation, as applied to the eclipses of Jupiter's satellites, that formed one of the data upon which the velocity of light was determined, and which led to the discovery of its progressive motion. The earth's motion, in reference to that of light, gives rise to the phenomena of *aberration*, for the earth will have moved a certain distance in her orbit during the time that a ray of light, which renders a star visible, is passing from it to the observer; consequently the *apparent* differs from the *real* place of a star.

Some bodies intercept light, or are *opaque*; others allow its transmission, or are *transparent*; and there are gradations from perfect opacity to nearly perfect transparency, as we see in *semitransparent* or *translucent* bodies.

But although we are in the habit of using the terms *perfect transparency* and *perfect opacity*, such states do not in fact exist; for the air, glass, water, and similar media, all arrest or absorb certain portions of light; whence it is inferred that perfect darkness may prevail in the depths of the ocean; and on the other hand, that the most opaque substances, if sufficiently attenuated or extended, would transmit light, as is the case with gold, and with exceeding thin laminæ of some other metals.

The transmission of light in right lines is evident from the phenomena of the shadows of opaque bodies, and its intensity diminishes as the squares of the distance. Thus, if an opaque screen one foot square be placed at a certain distance from a light, *a*, it will exactly shadow a second screen, two feet square at double the distance; a screen three feet square at thrice the distance, and one of four feet square at four times the distance; that is, the light concentrated upon the first screen would extend itself over four times the space, if suffered to fall upon the second, over nine times upon the third, and over sixteen times upon the fourth.

REFRACTION OF LIGHT.—When a ray of light passes through the same medium, or when it passes perpendicularly from one transparent medium into another, it continues to move without changing its direction; but when it passes *obliquely* from one medium into another of a different density, it is thrown more or less out of its old direction, and is said to be *refracted*. The refraction is *towards* the perpendicular when the ray passes into a denser medium, and *from* the perpendicular when it passes into a rarer medium. The medium in which the rays of light are caused to approach nearest to the line perpendicular to its surface, is said to have the greatest refractive density.

In the following diagram, fig. 88, *a* represents the oblique ray passing through *air*, and entering *water* at *b*, and *glass* at *c*, and emerging into the *air* at *a'*. *p.p* is a perpendicular line, towards which the ray is refracted, in the medium *b*, and to a still greater extent in the denser medium *c*; but

on again emerging into air at a' , it turns from the perpendicular, and resumes its former line of passage.

We accordingly find that when the ray a traverses one and the same medium, differing in different parts in its *density*, it will suffer a deflection in various parts of its course proportionate to the density of the medium. We know that the density of the atmosphere is greatest at the earth's surface, and that it decreases as we ascend, gradually becoming more and more attenuated; hence, supposing the temperature uniform, the refractive power of the atmosphere would be greatest at the earth's surface, and gradually diminish as we recede from it; a ray of light, therefore, passing obliquely from a celestial object and falling upon this variable atmosphere, would be gradually more and more bent in its passage through it, and move in a curved line, exactly as if the atmosphere consisted of an infinite number of layers, gradually increasing in density from above downwards.

88

It is this deflection, or refraction of light, that causes bodies to appear bent or distorted when viewed through transparent media, such as water or glass: an object, for instance, seen through a prism, seems more or less thrown out of its real place; and a stick, plunged into water, looks as if it were bent or broken. For the same reason, a piece of money, placed at the bottom of a basin, appears to be raised when water is poured upon it; so that if, in the first instance, the eye be so placed, in reference to the edge of the basin, as just to see the further edge of the coin, on pouring water into it, the whole of it will be visible: by spirit of wine it will appear to be still more raised than by water; and by oil, more than by spirit.

In viewing objects, therefore, through refracting media, they are always more or less thrown out of their real places; and, in consequence of atmospheric refraction, the sun and stars are visible before they actually emerge from, and after they have sunk beneath, the horizon; and as, on the one hand, in consequence of the progressive motion of light, and the great distance of the objects, celestial phenomena are not seen till an appreciable time after their actual occurrence; so, on the other, in consequence of refraction by the atmosphere, they are not seen in their real places; with the exception, indeed, of stars in the zenith. These displacements are so trifling as to be disregarded in ordinary cases, but they require strictly to be taken into the account in astronomical calculations.

The ultimate direction of a refracted ray of light is influenced by the relative position of the surface of the refractor, both at its point of entrance and exit. Thus by refraction at convex surfaces the rays may be converged to a focus, as by a common lens, the refraction in these cases taking place, as if each ray fell upon a plane surface tangent to the curve at the point of incidence.

The density of bodies is by no means the only circumstance that affects their refractive power, it also depends upon their chemical nature; and,

generally speaking, those substances have the greatest refractive power which are combustible, or which contain an inflammable basis. Nor is the refractive power of *compounds* the mean deduced from that of their components; which, however, it generally is, in mere *mixtures*. Hydrogen, sulphur, phosphorus, diamond, bees'-wax, amber, oil of turpentine, camphor, linseed oil, and olive oil, have refractive powers from two to seven times greater in respect to their density than those of most other substances. Newton, observing the high refractive power of the diamond, inferred that it was "an unctuous substance coagulated," long before its combustibility and real nature were known. This law seemed at one time to be opposed by an observation of Dr. Wollaston respecting *phosphorus*, which led him to ascribe to it a low refractive power; but Sir D. Brewster, confiding in the truth of the generalization, found, by forming it into prisms and lenses, that its refractive power was double that of the diamond when compared with its density. The following is a table of the refractive powers of many of the gases and vapours, that of atmospheric air being 1000, from the experiments of Dulong.—(*Bulletin Philom.* 1825; *Ann. de Ch. et Phys.*, xxxi., 154; *Gmelin Handbuch*, i. 139.) If the refractive power is directly as the density and inflammability (implying by that term, attraction for oxygen or electro-positive power,) it is, perhaps, = the product of the density into the inflammability; in which case the latter will be found by dividing the refractive power by the density; and, in column E, hydrogen presents itself as the most electro-positive, and oxygen as the most electro-negative, body, and the other quotients agree with this, excepting nitrous oxide, which appears more electro-positive than nitrogen. It appears from column C, that the actual refractive power of a compound exceeds the calculated, when the compound is neutral or alkaline, but falls short of it when it is acid, which also indicates an electro-chemical relation to it.

A	B	C	D	E
Air	1.000		1.000	
Oxygen	0.924		1.103	0.83
Hydrogen	0.470		0.068	6.89
Steam	1.000	0.933	0.625	1.60

Ammonia	1.309	1.216	0.591	2.22
Cyanogen	2.832		1.818	1.55
Hydrocyanic vapour	1.531	1.651	0.944	1.62
Alcohol vapour	2.220		1.613	1.37
Ether vapour	5.280		2.580	2.05
Muriatic ether vapour	3.720	3.829	2.234	1.67

[In the preceding column A specifies the gas, B its refractive power determined by experiment, air being = 1. C shows the calculated refractive power, deduced from that of the component gases. D the density compared with air. E the quotient of the refractive power divided by the density.]

The following are the refractive powers of several gaseous bodies, from the experiments of Biot and Arago, at the temperature of 32° F., and under mean barometrical pressure, corresponding to column E of the preceding table.

Atmospheric air	1.00000	Ammonia	2.16851
Oxygen	0.86161	Carbonic acid	1.00476
Nitrogen	1.03408	Carburetted hydrogen	2.09270
Hydrogen	6.61436	Muriatic acid gas	1.19625

Dr. Wollaston invented an apparatus in which, by means of a rectangular prism of flint-glass, the index of refraction of substances may be read off at once by a vernier, the three sides of a moveable triangle performing the operation of reduction in a very compendious manner. As the chemical constitution of bodies may in many instances be inferred from their refractive power, Dr. Wollaston has suggested the application of such an instrument for discovering the purity of essential oils: in oil of cloves, for instance, he found a wide difference in refractive power, that of the genuine oil being as high as 1.535, while other samples did not exceed 1.498, and were probably adulterated. (*Phil Trans.* 1802.) In thus employing this instrument, however, it must be recollected that the refractive power of the same oil distilled at different times will vary, this, at least, I have found to be the case with oil of peppermint.

The following table shows the refractive powers of several liquids and solids.—(DANIELL, § 225.)

Sulphuret of Carbon	1.678	Chromate of lead	2.974
Tolu balsam	1.628	Diamond	2.439
Castor oil	1.490	Phosphorus	2.224
Almond oil	1.483	Calcareous spar	1.654
Oil of turpentine	1.475	Quartz	1.548
Sulphuric acid	1.434	Rosin	1.559
Alcohol	1.372	Rock salt	1.557
Ether	1.358	Ice	1.308
Water	1.335	Tabasheer	1.111

REFLECTION OF LIGHT.—When the rays of light arrive at the surfaces of bodies, a part of them, and sometimes nearly the whole, is thrown back, or *reflected*, and the more obliquely the light falls upon the surface, the greater in general is the reflected portion. In these cases the angle of reflection is always equal to the angle of incidence. Suppose a ray of light to impinge *perpendicularly* upon the surface of a mirror, as at *r m*, but one ray is seen, for the ray of incidence and that of reflection are both in the same line, though in opposite directions, and they are confounded together. The ray therefore which appears single, is, in fact, double, being composed of the incident ray proceeding to the mirror and the reflected ray returning from it. These rays may, however, be separated by so holding the mirror that the incident ray,

a m , shall fall *obliquely* upon it. in which case the reflected ray, $m b$, is thrown off in the opposite direction. If a line be drawn from the point of incidence, perpendicular to the mirror (as the line $m r$), it divides the angle of incidence from the angle of reflection, and both are seen to be equal.

When rays of light fall upon a concave mirror, they are reflected as if from a series of planes tangents to that surface, and may thus be *converged* to a point or focus; when, on the other hand, the rays fall upon a convex mirror the convergency of the rays is diminished, and their divergency increased.

§ 13.—DOUBLE REFRACTION AND POLARIZATION OF LIGHT.

IN all cases of the *ordinary* refraction of light, the ray by which we see an object through a refracting medium, although bent, yet, in pursuing its course to the eye, does not quit a plane perpendicular to the refracting surface: the plane in which the eye, the object, and the point on the surface of the medium in which the object is seen are contained, is an upright, or vertical plane. (See HERSCHEL'S *Discourse*, p. 30.) But there are certain *crystalline* substances, as rock-crystal, &c., but especially *Iceland spar*, which possess the remarkable property of *doubling* the image, seen through them in certain directions; so that, instead of seeing one, we see two, side by side, when such a crystal is opposed between the object and the eye: and if a ray, or small sunbeam, be thrown upon a surface of this substance, it will, on traversing it, be split into two, making an angle with each other, and each pursuing its own separate course.

Having obtained a rhomb of Iceland spar, fit for these experiments, place it, as shown in fig. 90*, above a sharp line, and look through it with the eye about R. The line will appear doubled, like $mnpq$. So also a dot will be doubled, as eo . If we cause a ray or pencil of light, R, r , to fall upon the surface of the rhomb. it will be separated into two rays or pencils, ro, re each of which will emerge from the rhomb at o and e ,

in the directions oo' and ee' parallel to rr . The ray Rr , therefore, has suffered *double refraction* in passing through the rhomb: and as the very same phenomena will take place by making the ray Rr fall at the same incidence and in the same direction, relative to the summit A, upon any point of the faces, it is manifest that the double

refraction cannot arise from any difference of density in different parts of the rhomb.

* See *Library of Useful Knowledge*, on the double refraction and polarisation of light.

Of the doubly-refracted rays, *one* always appears to follow the same rule as if the substance were glass or water, and retains the plane perpendicular to the refracting surface: the other ray, on the contrary, which is therefore said to have undergone *extraordinary refraction*, does quit that plane, and its deviation becomes subject to a new law. It has, however, been demonstrated by Fresnel, that in the greater number of instances of double refraction by crystalline bodies, neither of the images follows the ordinary law, but both undergo a deviation from their original plane, and acquire new properties, and this is the case with respect to Iceland crystal, as we shall presently find; we may, however, continue the terms *ordinary* and *extraordinary ray*, for convenience sake.

Some remarkable effects accompanying double refraction, led Newton to conceive the singular idea, that a ray of light, after emerging from the crystal, acquires *sides*; that is, distinct relations to surrounding space, which it carries with it through its whole subsequent course, and which give rise to all those complicated and curious phenomena now known under the term *polarization of light*. This idea, however, appeared so extraordinary, and as Sir J. Herschel remarks, offered so little handle for further inquiry, that the subject dropped, till Malus, in 1810, announced the discovery of the *polarization of light by ordinary reflection*, at the surface of a transparent body. He found that when a beam of light is *reflected* from the surface of such a body, *at a certain angle*, it acquires the same singular property which is impressed upon it in the act of double refraction, and the phenomena of polarization are in this way more conveniently exhibited*.

In general, when a ray of light is reflected from a pane of plate-glass or other polished surface, it may be reflected a second time from another surface; it will also pass freely through transparent bodies: but if a ray of light be reflected from a pane of plate-glass, at an angle of 57° , it is rendered incapable of reflection at the surface of another pane of glass, in certain definite positions, but is reflected by it in other positions: it also loses the power of passing through some transparent bodies in certain positions whilst in others it is freely transmitted by them.

If a prismatic crystal of transparent brown *tourmaline*, be cut longitudinally (that is parallel to the axis of the prism) into plates about the thirtieth of an inch thick, and the surfaces polished, luminous objects may be viewed through them. If one of these plates be held perpendicularly between the eye and a candle, and turned slowly round in its own plane, no change will take place in the image of the candle; but, if the plate be held in a fixed position, with its axis or longitudinal section vertical, when a second plate is interposed between it and the eye, parallel to the first, and turned slowly round in its own plane, a remarkable change is observed in the nature of the light, for the image of the candle vanishes and reappears alternately at every quarter of a revolution of the plate, varying through all degrees of brightness, down to total, or almost total evanescence, and then increasing again as it had before decreased. These appearances depend upon the relative position of the plates: when their longitudinal sections are parallel, the brightness of the image is at its

* The following details connected with this subject, I have abridged from Mrs. SOMERVILLE's *Connexion of the Physical Sciences*, Section xxii.

maximum, and when they cross at right angles it vanishes. Thus, the light, in passing through the first plate of tourmaline, has acquired a property totally different from the direct light of the candle: the direct ray would have penetrated the second plate in all directions, whereas the refracted or *polarized* ray penetrates it in certain positions only, and in others is wholly obstructed. The plate of tourmaline therefore becomes, when applied as above directed, a test of the polarization of the ray. If we now look at the two images produced by the Iceland spar, through a plate of tourmaline, it will be found, that as the tourmaline revolves, the images vary in their relative brightness; one increases in intensity till it arrives at a maximum, whilst the other diminishes till it vanishes, and so on alternately at each quarter of a revolution, showing that *both of the images are polarized* in opposite directions, for in one position the tourmaline transmits the ordinary ray, and reflects the extraordinary; and after revolving 90° , the extraordinary ray is transmitted, and the ordinary ray is reflected.

If a pane of plate-glass, with its lower side blackened, or lying upon a piece of black cloth, be placed on a table, and a candle near it, the rays of which fall upon the glass at an angle of 57° , it will be found that they are reflected from the surface in a polarized state, for, on viewing the image through the revolving slice of tourmaline, it will disappear at every quarter of a revolution. It is also found that this polarised ray is incapable of being reflected a second time from another plate of glass, placed at the same angle. If, for instance, the second plate be so placed as to make an angle of about 57° with the reflected ray, the image of the first pane will be reflected in its surface, and alternately illuminated or obscured at every quarter of a revolution of the second plate, according as its plane of reflection is parallel or perpendicular to the plane of polarization. Hence, polarized light is shown to be incapable of reflection in a plane at right angles to the plane of polarization. These, and some other curious phenomena of polarized light are easily shown by the following arrangement of apparatus. Let two plates of glass, blacked on the back, AC, be arranged as in the following diagram, fig. 91, so that the rays from a candle at R, falling upon the first or *polarizing* plate, A, at its angle of polarization, may not be reflected by the second or *analysing* plate, C. This adjustment may be made by looking into C in the direction of FC,

and finding the image of the candle wanting; then take a thin film of mica, or sulphate of lime, DEFG, and place it between the two plates,

perpendicular to the polarized ray. It will then be found, on turning this plate upon its axis, that the image of the candle disappears, and reappears at each quarter of a revolution; or, in other words, that in certain positions it *depolarizes* the ray. Common glass is generally incapable of effecting this depolarization, but it acquires the depolarizing power when submitted to pressure, or heated, or when it has been heated and very suddenly cooled; the influence of its particles upon those of light becoming then analogous to crystallized bodies. If we now view the polarized image through a plate of tourmaline, with the interposed plate of mica, a succession of beautiful colours will appear in certain positions of the mica, depending upon the thickness of the plate: these colours succeed each other in definite order, and are complementary to each other.

Different reflecting surfaces polarize light at different angles: thus the angle for water is $53^{\circ} 11'$; for glass $56^{\circ} 45'$; for rock crystal $56^{\circ} 58'$; for Iceland spar $58^{\circ} 51'$; for diamond $68^{\circ} 1'$; for sulphur $63^{\circ} 45'$.

In the preceding details, my object has been merely to explain the meaning of the term *polarization*, as applied to certain properties of light; those who would pursue the inquiry will find it amply treated of in the communications of Sir David Brewster to the Royal Society (*Phil. Trans.* 1813, &c.), and in various treatises to which references are given in the authorities which I have had occasion to quote. I must also refer to the same sources, for the discussions to which the investigations connected with the subject have given rise, respecting the nature of light; they are extremely curious and important, especially as illustrative of the applications of the undulatory theory.

§ 14.—DECOMPOSITION OF LIGHT.

THAT a sun-beam, in passing through certain dense media, gives rise to a series of brilliant tints, similar to those of the rainbow, was known in the earliest ages, but Newton first explained and investigated the phenomena. He admitted a ray of light, *r*, fig. 92, through a hole in the window-shutter, *w*, of a dark room, and caused it to fall upon a glass prism, *P*, by which it was refracted, and resolved into *seven* colours, which formed an oblong image or *spectrum* upon the white screen, *s*, in the order represented, namely, red, orange, yellow, green, blue, indigo, and violet. Had the ray proceeded straight onwards it would have formed a luminous spot at *x*, it is, therefore, seen that of these coloured rays, the *violet* have undergone the greatest refraction, and the *red* the least, and that they are arranged in the order of their refrangibility.

Newton submitted each of these rays to repeated refractions, but found that they were not resolvable into simpler colours; but, on causing them to pass through a second prism

in an inverted position *Q*, or by collecting them into one focus by means of a lens, they were reunited and again produced *white light*; whence he inferred white light to consist of these seven simple or primitive colours. With the prism which he used, (of flint glass,) the respective lengths of the colours (dividing the spectrum into 360 parts) were as follows:—red 45, orange 27, yellow 40, green 60, blue 60, indigo 48, violet 80. These spaces, however, cannot be very accurately defined, as the colours imperceptibly shade into each other: they also vary with prisms of different substances. The composition of white light by the union of the above colours, may be also shown by mixing seven different powders, having the colours and proportions mentioned; or more readily, by painting the rim of a wheel with the seven colours, which, when in very rapid motion, appears white, or nearly so*.

The *colours* of bodies were referred by Newton to their relative absorbent and reflective powers, in respect to these rays; he supposed *black* surfaces to absorb, and *white* to reflect them all, and that other colours are produced by the absorption of all the rays except those of the observed colour, which are presumed to be reflected. And in respect to transparent media, those which are colourless suffer the light to pass unchanged, while those which are coloured, transmit some rays, and absorb others. The absorption of coloured rays, therefore, by certain media, furnishes another means of analysing light, and from experiments conducted in this way, Sir David Brewster has been led to conclude that the only colours of the spectrum which can properly be called *simple*, are the red, yellow, and blue; that they are concentrated in those parts of the spectrum where each appears, but that they are also spread more or less over the whole, and that the orange results from a mixture of red and yellow; the green, from a mixture of yellow and blue; and the violet and indigo from red and blue, with a trace of yellow.

The length of the spectrum depends upon the nature of the prism or refracting medium; thus, if obtained by a hollow prism of glass, filled with oil of cassia, it is much longer than when glass only is used; hence the oil of cassia is said to *disperse* the rays more than glass, or to have a greater *dispersive power*. In such cases, also, the coloured spaces bear a very different ratio to each other.

It appears from the experiments of Sir W. Herschel, (*Phil. Trans.*, 1800,) that the greatest *illuminating* power of the spectrum is in the brightest yellow, and that it decreases towards either extremity, the blue and red being nearly equal, and the violet inferior to both.

A curious fact respecting the prismatic spectrum, when very perfect, and the sunbeam small, was discovered by Professor Frauenhofer, of Munich; he observed it to be irregularly subdivided by a number of black lines; they are so narrow as to escape observation without great care; they are seen when the spectrum is received upon the object-glass of a telescope, or by viewing a narrow slit between two nearly-closed shutters,

* The impression of light upon the retina of the eye continues for about an eighth part of a second, so that a luminous point revolving with a velocity sufficient to complete the circle within that time, appears not as a point, but as a circle of light, the impression made on it in every point of its revolution being retained for the above time.

through a very perfect prism, held close to the eye, with its refracting angle parallel to the line of light. They are always found in the same parts of the spectrum, of the same breadths and intensities. They are very numerous, amounting to some hundreds; from these, Fraunhofer selected seven, and determined their distances so accurately, that they form invariable points of reference for measuring the refractive powers of different media. They are also seen in the light of the stars, in electric light, and in the flame of combustible substances, though in each case differently arranged, each having a system of them peculiar to itself, and remaining the same under all circumstances.

§ 15.—CHEMICAL EFFECTS OF THE SOLAR RAYS.

THE object of the preceding sections has been to give an outline of the principal physical properties of light, or at least of such of them as have bearings upon chemistry. We may now proceed to the consideration of some other phenomena connected with, or dependent upon, the solar rays.

No one can have failed to observe the differences between *vegetables* thriving in the full enjoyment of solar light, and those which grow in obscure situations, or which are entirely deprived of its agency. The former are of brilliant tints, the latter dingy and white; in the one, the various secretions come to perfection; in the other they are either modified or disappear. Of this, numerous familiar instances might be cited, especially among our esculent vegetables. The shoots of a potato produced in a dark cellar are white, straggling, and differently formed from those which the plant exhibits under its usual circumstances of growth. Celery is cultivated for the table by carefully excluding the influence of light upon its stem: this is effected by heaping the soil upon it so as entirely to screen it from the solar rays; but if suffered to grow in the ordinary way, it soon alters its aspect, throws out abundant shoots and leaves, and instead of remaining white and of little taste, acquires a deep green colour, and a peculiarly bitter and nauseous flavour. The interior, or heart of endive is not eatable, unless protected from light; if exposed to it, it becomes disagreeably bitter and tough. The heart of the common cabbage is another illustration. The rosy and coloured aspects of the side of fruits exposed to the sun are referable to the same cause. Changes yet more remarkable have been observed in plants vegetating entirely out of the access of light. In visiting a coal mine, Professor Robinson found a plant with a large white foliage, the form and appearance of which were quite new to him: it was left at the mouth of the pit, when the subterranean leaves died away, and common tansy sprung up from the root.

In the *animal creation* the influence of light is equally evident. It is curious to remark the dull and dingy tints of polar and subterranean animals, as contrasted with the gaudy and brighter colours of those which inhabit the tropical regions of the globe, and enjoy the full sunshine. In the human species, too, a due quantity of light is requisite to health; miners are generally pallid and unhealthy; and the inhabitants of the dark alleys and courts of London indicate a similar want of its beneficial

influence; though in these cases, bad air and poor diet also contribute to want of health.

In reference to the above and other effects of light upon plants, there can be little doubt that they chiefly depend upon its power of modifying the chemical changes, which are constantly carrying on in the vegetable kingdom; but the common operations of the laboratory furnish us also with some striking illustrations of *the influence of light in promoting the chemical agencies of bodies.*

Hydrogen and *chlorine* are two gases, which, when mixed and kept in the dark, are nearly without action; but if exposed to the light of day, they soon act upon each other, and unite to form *hydrochloric acid*; and if the sun shines directly upon the bottle containing them, it not unfrequently happens that they inflame and explode in consequence of the energy imparted to their attraction by the solar rays. We have an analogous instance in *chlorine* and *carbonic oxide gas*, which, when mixed together, remain without action till exposed to light; they then combine chemically with diminution of volume, and produce a compound, which, from the mode of forming it, has been termed *phosgene gas*. In the same way also, chlorine and water react rapidly upon each other in the sunshine, forming hydrochloric acid and evolving oxygen.

Some of the salts of gold and of silver, especially their chlorides, are remarkably susceptible tests of the chemical agency of light: the *nitrate of silver* may be selected by way of illustration. If a piece of paper be dipped into a solution of this salt, and kept in the dark, it suffers no apparent change; but if exposed to light, it soon becomes purple, brown, and black, changes of colour depending upon a chemical change suffered by the salt. A pretty experiment, showing the action of light upon nitrate of silver, was devised by Mr. Wedgwood: a piece of paper, or other convenient material, was stretched upon a frame and sponged over with a solution of the salt; it was then placed behind a painting upon glass; and the light, traversing the painting, produced a kind of copy of it upon the prepared paper; those parts in which the rays were least intercepted being of the darkest hues. Many improvements in these *photogenic drawings*, as they have been termed, have been effected more especially by Mr. Fox Talbot, Sir John Herschel, and Mr. Alfred Taylor, some of the details of which will be found under the head of *SILVER*; as also an account of the extraordinary phenomena discovered by M. Daguerre, in reference to the action of light upon a surface of silver covered by a film of iodine.

Scheele was the first to whom the ingenious idea occurred of ascertaining whether all the rays possessed similar chemical powers, or whether they belonged more exclusively to one colour than to another; and he found, upon refracting a beam by the prism into its primary colours, and throwing them upon a piece of paper prepared with nitrate of silver, that the greatest blackening effect was produced by the *violet ray*, and that the decomposing or chemical powers of the prismatic *spectrum*, gradually decreased towards the red ray, where scarcely any effect was produced. This result was quite contrary to expectation; for one would, of course, have anticipated the greatest effect in the most luminous part of the spectrum.

It was afterwards discovered by Wollaston and Ritter, (*Phil. Trans.*, 1802, and *Philos. Journal*, iv. and viii.,) that certain *invisible* rays, occupying a place in the spectrum just beyond the violet extremity, possessed a greater power of effecting the above and other chemical changes, than the violet rays themselves; and it has, consequently, been inferred that such distinct rays emanate from the sun, possessed, as their place in the spectrum shows, of great refrangibility: and that the coloured rays (and their mixture, constituting white light,) derive their chemical powers from the admixture of these highly refrangible and chemically acting rays, which are most abundant at the blue end of the spectrum, and gradually decrease towards the red or least refrangible rays. Thus, it was found that the greatest blackening effect upon the salt of silver was produced just beyond, and out of the violet ray: the other peculiar chemical effects to which we are now adverting were also most manifest in the same spot, It must, however, be observed, that the place occupied by these rays in the spectrum, depends, in some measure, upon the nature of the medium by which the light is refracted.

Berard found, that in the focus obtained by concentrating the rays of one-half of the spectrum (the red end), chloride of silver was not blackened, though the light was very brilliant; but that, in the darker focus from the violet half, it was immediately discoloured. Seebeck, by exposing chloride of silver to the red ray, found that it gradually acquired a pale rose colour; and that the rays coloured by transmission through coloured glasses, produced the same general effects as the differently coloured rays of the spectrum. He also found that a piece of paper, dipped in a neutral, and not too-concentrated solution of gold (which is reduced by light), underwent no change when preserved in the dark, provided it had not been previously exposed to light; but that, if exposed for a short time to the sun's rays, though not at the moment discoloured, and then kept in a dark place, it gradually became purple, and the gold was reduced. Ritter and Davy have assumed that the opposite ends of the spectrum possess opposed chemical powers, something like the opposed electrical poles, but of this we have, as yet at least, no satisfactory experimental evidence; it is true that Wollaston found a piece of paper stained yellow with tincture of guaiacum, to become green in the violet ray, and again yellow in the red; but he afterwards found that the mere heat of the red ray produced the effect; and many vegetable colours are as effectually bleached by heat as by light.

Many years ago, Morichini thought that he had communicated *magnetism* to steel-wires, by exposing them to the rays of violet light. So curious a result attracted much notice, and his experiments were repeated by several eminent philosophers with very various success: it was generally, however, presumed that he was mistaken in his conclusions, and that the needles had acquired magnetism from some other sources. The subject was afterwards resumed by Mrs. Somerville, (*Phil. Trans.*, 1826,) who, from a series of apparently well-conducted experiments, arrived at the same conclusion as Morichini. It must however, be confessed, that there are many difficulties in the way of attaining perfectly unexceptionable results in these experiments; and whether magnetism is, or is not, producible by the sole influence of light, is a question not definitively

settled, unless, indeed, the experiments of Messrs. Riess and Moser (*Edin. Journal of Science*, II., 225,) be considered conclusive in disproving it.

§ 16.—OF RADIANT MATTER AS A SOURCE OF HEAT.

Different parts of the prismatic spectrum have different heating powers.—If we cause the spectrum to fall upon a sheet of paper, and gradually pass the hand through it, from the violet to the red end, we shall perceive the latter to be sensibly warmer than the former; and, on applying a delicate thermometer in the differently coloured rays, it will be found scarcely affected by the blue; in the green it rises; and in the red, shows an increase of several degrees of temperature. Assuming the heating power of the violet rays, = 16° , that of the green is = 26° , and of the red = 55° .*

The observation of this fact suggested to Sir W. Herschel the possibility of the heating power of the spectrum extending *beyond* the red ray, and, on applying a thermometer just out of the red ray, and beyond the limits of the visible spectrum, this was found to be the case. A thermometer in the red ray rose *seven* degrees in ten minutes, but just *beyond* the red ray, the rise in the same time was *nine* degrees. *Phil. Trans.*, 1800†.

In these, as in the former experiments, the effects are modified by the nature of the prism used to refract the light: when it is of flint glass the phenomena are as above described; but, with crown glass, water, and other refracting media, the position of the heating or calorific rays varies.

It appears, then, that the radiant matter of the sun is resolvable, by refraction, into three distinct sets of rays; those producing *colour*; those which effect certain *chemical changes*; and those which excite *heat*; the chemically acting rays are the *most* refrangible, the calorific rays the *least* so, and the colorific rays, or those producing light and colour, possess a *mean* degree of refrangibility. All these rays are susceptible of refraction and reflection, as is proved by their concentration into a focus by a concave mirror or a lens; in which case, in consequence of their different refrangibilities, the heating and chemically acting focus is probably not identical with the luminous focus. From the experiments of Berard, Melloni, and Professor Forbes, the chemically acting and the heating rays are also susceptible of the phenomena of polarisation.

§ 17.—TERRESTRIAL RADIATION, AND THE INFLUENCE OF VARIOUS SURFACES UPON THE RECEPTION AND EMISSION OF RADIANT MATTER.

WE use the term *terrestrial radiation*, to designate the heat and light thrown off by terrestrial bodies under certain circumstances, especially at high temperatures, as when they are red-hot, or burning; that is, in a state of *ignition*, *incandescence*, or *combustion*. We also well know that

* Hence the idea of the different-coloured rays, consisting of light in combination with different proportions of heat.

† See also the repetition of these experiments by Sir H. Englefield, and by M. Berard. (*Thomson's Annals*, II., 163.)

terrestrial heat radiates from bodies at temperatures far below those required for ignition. If, for instance, I fill a jug with hot water, I feel heat emanating from it to my hand when held near it. All these subjects may be discussed under the head of *terrestrial radiant matter*.

The rays which emanate from heated bodies, whether attended or unattended by light, may be *reflected* in the same way as the solar rays, and the phenomena connected with this kind of radiation are, in many respects, extremely curious and important: they are also susceptible of many economical applications, for in this country it is to radiant heat that we are chiefly indebted for the warmth and comforts of our apartments in winter; the construction of our grates, and fire-places in general, being such as to carry away the whole current of the heated air by the chimney, and prodigally waste it in the atmosphere; they consequently produce their warming effects, by the heat which emanates from the burning fuel and heated surfaces, and is projected or radiated upon the surrounding bodies in the room.

Several important facts upon the subject of the radiation of heat were established many years ago by Scheele (in his treatise on *air and fire*, originally published in 1777). He observed, that radiant heat passes through air without communicating heat to that medium, and that it is not intercepted by currents in the atmosphere. He then proceeded to ascertain how far it coincided with *solar* heat, in passing through glass, and found that, although the *light* of a fire or of a candle passed through it, their *heat* was arrested, or stopped in its progress. It was thus thought that a decided difference was established between solar and terrestrial heat; but we shall find that, in reference to this experiment, it is rather apparent than real, and due to the small quantity, or intensity of the latter, as compared with the former. He also found that, when a *glass* mirror is held before the fire, the light only is reflected, while the heat is absorbed, and the mirror itself becomes hot; but when for glass we substitute a mirror of *polished metal*, then, both the heat and the light are reflected, and the metal itself not heated: if, however, the surface of the metal be covered with some other substance, if it be smoked, for instance, by holding it over a burning candle, then the surface *absorbs* the rays of heat, and the mirror of metal, like that of glass, becomes itself hot.

These observations of Scheele led Leslie and others into the same path of inquiry, and we have, upon the whole, a very satisfactory series of experiments upon the subject, of which the following is an outline, as far as the principal facts are concerned:—

That heat radiates from bodies in right lines, and is susceptible of reflection, is shown by placing two polished concave mirrors, made of planished tin, or, what is better, of plated copper, exactly opposite to each other, and about ten feet asunder. For experiments upon a large scale, the mirrors should be at least of two feet diameter, but common tin mirrors or reflectors of one foot are sufficient for all common illustrations. A heated body, such, for instance, as an iron-ball, or a flask of boiling water, is placed in the focus of one mirror, and an air-thermometer in that of the other*. The rays of heat then impinge on the one mirror,

* The foci of the mirrors are best found by the help of a lighted candle, the heating focus corresponding with the luminous one; and in these experiments

and are *reflected*, consistently with the property of concave mirrors, in parallel lines, so as to fall upon the opposed mirror, whence they converge to its focus, in which is the thermometer, and which is affected proportionately to the heat of the original radiating body.

Let A, fig. 93, represent the first mirror; B the second; c the heated sphere or flask, and d the air-thermometer; the dotted lines show the direction of the calorific rays.

To prove that the thermometer is not affected by the *mere proximity* of the heated body, independently of any actual *reflection* let a sheet of pasteboard be held between the mirror B and the thermometer; the latter will immediately indicate the absence of the quantity of heat it before received, notwithstanding the source is as near to the bulb as it was before. If we even carry the ball a little out of the focus of the mirror A, by advancing it gently towards the thermometer, a diminution of heat will be perceived in the latter, in consequence of the disturbance of the most favourable arrangement for reflection. Indeed, the distance between the heated ball and the air-thermometer is such, that notwithstanding the delicacy of the latter instrument, it would not be affected, as may again be shown by removing one or both of the mirrors, and leaving the ball and thermometer in their same relative positions.

Radiation goes on from surfaces in all elastic media, and in vacuo, and is no way connected with aerial pulsations. By igniting points of charcoal by the voltaic battery in the focus of a small mirror confined in the exhausted receiver of the air-pump, Sir H. Davy found, that the receiver being exhausted to $\frac{1}{12}$ of the atmosphere, the effect upon the thermometer in the opposite focus was nearly three times as great as when the air was in its natural state of condensation. a, fig. 94, is the receiver, bb the insulated wires connected with the voltaic apparatus igniting the charcoal in the focus of the upper mirror c. In the focus of the lower mirror d is the thermometer e. A part at least of this increased effect is probably due to the increase of heat sustained by the charcoal, when thus ignited in vacuo, as compared with that which it acquires in the air.

the *differential thermometer* above described is most satisfactorily employed, for it is not affected by currents or ge-

neral changes in the temperature of the room in which the experiments are made.

If, for the hot bullet, or flame of a candle, or flask of boiling water, we substitute some more copious source of heat, the effects will be proportionately great. If we, for instance, place a wire-basket full of burning charcoal, or a piece of red hot iron in one focus, and a piece of phosphorus in the other, the latter will be immediately inflamed; in the same way fulminating silver may be exploded, a mixture of chlorate of potassa and sulphuret of antimony inflamed, and even gunpowder kindled. And for such experiments we may adopt Sir H. Davy's plan of placing the mirrors vertically, as shown in fig. 95; the little chafing-dish is in the focus of the upper mirror, so that all the heat that reaches the lower mirror, and is concentrated in its focus, must be radiant and reflected, for the current of heated air will pass upwards and be lost.

For the conjugate mirrors we may occasionally substitute a sheet of burnished gold or silver paper, twisted up into the form of a truncated cone, with the metallic surface inwards: on holding its larger end towards a clear fire, or before a heated ball of iron, the radiant heat will be reflected so as to form a focus beyond the smaller end, where a piece of phosphorus or a lucifer match may be kindled.

The intensity of the calorific, as well as that of the luminous rays, decreases as the squares of the distance from the substance whence they emanate. A thermometer, for instance, placed at the distance of one foot from a heated body, will indicate the reception of four times more heat than at two feet, of nine more than at four feet, and of sixteen times more than at three feet. (See fig. 87.)

If we substitute a *cold body* for the heated one, a lump of ice, for instance, sprinkled over with salt, or a thin glass flask, containing a mixture of snow and salt, we shall then observe the thermometer in the opposite focus to be affected by *cold*; and this experiment has sometimes been adduced to prove that cold is a distinct form of matter. It has been supposed that highly attenuated emanations are at all times passing off from the surfaces of all bodies, under the form, and producing the effects of, *radiant matter*, the temperature excited by which depends upon that of the emanating body: that hot bodies radiate heat: that we perceive no effect from bodies at common temperatures, because their radiant matter is of the same temperature as that of the thermometer

or substance upon which they fall: but that cold bodies, on the contrary, throw off cold radiant matter, and hence their effect upon the thermometer. It has been assumed that the actual radiation of cold is proved by placing a plate of snow or bruised ice near the face, when an effect of cold is immediately perceived, and may be intercepted by a sheet of paper or other screen: that *temperature* therefore is merely a relative term: and that we may suppose ourselves in a temperature so high, that red-hot iron would radiate cold; or, again, in a temperature so low, that ice would radiate heat.

Sir. H. Davy observes, in reference to this subject, which he calls the *apparent* radiation of cold, "that if it be supposed that rays capable of producing heat emanate from all terrestrial bodies, but in quantities greater in some increasing proportion as their temperatures are highest, then the introduction of a cold body into the focus of one mirror, ought to diminish the temperature of a thermometer in the focus of the other, in the same manner as a black body placed in one focus would diminish the quantity of light in the other focus; and the eye is to the rays producing light, a measure similar to that which the thermometer is to rays producing heat." (*Elements*, p. 206.) Dr. Turner observes, that "the thermometer has its temperature lowered because it emits more rays than it receives, and it rises when the ice is removed, because it then receives a number of calorific rays, radiated by the warmer surrounding objects which were interrupted by the ice whilst it was in the focus." Mr. Daniell says, "the thermometer is the hotter body, and radiating its heat upon the nearest mirror, the rays are projected upon the second, and collected in the focus, where they are absorbed by the ice; and as no adequate return is made, the temperature of the thermometer necessarily falls."

INFLUENCE OF DIFFERENT SURFACES UPON THE RECEPTION AND EMISSION OF RADIANT HEAT.—It has been stated, that if a *polished metallic* mirror, of a concave or parabolic form, be held opposite the fire, it will give a heating focus, but that the mirror itself is long before it becomes sensibly warm; that is, the heat which impinges upon it, is immediately thrown off or *reflected*. If we now cover the surface of the mirror with an *unmetallic* coating, or merely roughen the surface, and then hold it towards the fire, a very different effect ensues, and now, the greater part of the radiant heat, instead of being thrown off, is *absorbed*, and soon heats the mirror. A mixture of chalk or lampblack and diluted glue or gumwater, answers very well for the above purpose.

Here, then, the *receptive* powers of surfaces, in regard to radiant matter, are shown materially to depend upon their nature or mechanical texture. In further illustration of this subject, a simple experiment may be made with the differential air-thermometer: let one of the glass bulbs, for instance, be nicely covered with a bright coating of gold-leaf, and leave the other in its usual state: place the instrument thus prepared upon a table, and bring a hot poker near it, taking care, however, that it is equally distant from both bulbs, or, if anything, rather nearer the metallic than the glass surface. Under these circumstances it will be found, that by far the greatest effect of heat is produced upon the *glass* ball, from which the fluid in the tube immediately recedes, notwithstanding

standing heat is equally applied to the gilt ball; the latter, however, refuses to absorb it, while the former imbibes it, and has its temperature proportionately augmented. If, instead of leaving the ball clean, it be covered with a thin coat of whitewash, or of lampblack, its receptive power will be still greater.

Although the *texture* of the surface is shown to be materially concerned in these results, it does not appear that *colour* in the least interferes; black-wash and white-wash are equally receptive of *terrestrial* radiant heat; nor does it appear to be absorbed in larger proportion by any one colour than by another.—(BACHE, *Journ. Franklin Institute*; May and November, 1835.) Dr. Stark indeed (*Phil. Trans.*, 1683) has endeavoured to show that *colour* does interfere in these cases; and he gives some curious statements respecting its influence upon the reception of *odours*; but it is possible that the texture and composition of the materials employed may affect the results; just as *white* silk is a much better insulator of electricity than *black* silk; not on account of colour, but of dye-stuff.

With regard to *solar* radiant heat, however, the case is different; and, as common experience teaches, *black* surfaces absorb it much more greedily than white, and the *temperature produced appears to be proportionate to the intensity of colour**. If pieces of cloth of different colours be exposed to the sunshine upon the surface of snow, the dark colours will sink into it, in consequence of the heat which they produce; the lighter colours scarcely effect the thawing of any portion; and white remains inactive. The difference between a white and black hat in heating the head, and between dark and light-coloured clothing in general, is well known to those who are much exposed to the summer's sun. Paint the bulb of one thermometer black, and of another white, and expose them to the sunshine; the former will indicate a higher temperature than the latter. A similar but more striking experiment may be made with the differential thermometer. Blacken one of the bulbs, and leave the other clean and transparent; if the instrument thus prepared be exposed to the sunshine, the excess of heat in the blackened ball is immediately indicated by the recession of the liquid from it to the clean ball. If the air thermometer be small and delicate, it is even susceptible of the mere impression of daylight, which, slightly augmenting the temperature of the black ball, depresses the fluid in the tube annexed to it. Hence the differential thermometer, thus constructed and applied, has been called a *photometer*†. Another illustration of

* It has hence been assumed, that the negro must suffer more from heat than the European; but it has been shown by Sir E. Home (*Lectures on Comp. Anatomy*), that the sun's rays are absorbed without ill effect, by the black rete mucosum, whereas they blister and scorch the white.

† Pictet first employed a blackened thermometer as a *photometer*. Leslie concluded, from his photometrical experiments, that the light of the sun pos-

sessed 12000 times the intensity of that of a wax-candle, so that a fragment of the sun, of the size of such a flame, would possess the illuminating power of 12000 candles. With the same instrument he determined the relative transparency of substances: thus he found, that of 100 rays of light, 80 passed through dry cambric, 93 through wet cambric, 49 through thin paper. 80 through oiled paper, &c.

this effect of solar rays, consists in placing a glass tube containing alcohol or ether in their focus, when collected by a lens; they traverse the transparent medium without heating it; but upon putting a piece of black paper into the liquid, or a strip of black wood or metal, it immediately boils. In this way water may be heated by directing the focus of a lens or mirror, exposed to the sun, upon good receptive and opaque surfaces immersed in it.

In many of the above statements there seems to be a manifest *difference* between solar and terrestrial radiant heat; but this is probably rather apparent than real; in the solar beam, radiant heat and light are combined, and when they fall upon dark surfaces are absorbed together. The quantity of radiant matter, too, emanating from the sun, is incomparably great in reference to anything produced artificially. The solar beam passes through a thin plate of glass without decomposition, and falling upon black surfaces upon the other side, is absorbed by, and heats them: but terrestrial radiant matter, emanating, for instance, from a lamp, or candle, or fire, suffers, in such case, a kind of decomposition; the *light passes* through the glass, but part of the *heat is stopped* in the progress; in the case of the sun's ray the transmitting glass is scarcely heated; in the other case, the glass becomes hot.

It was formerly supposed that terrestrial heat did *not* pass through glass, and that glass screens were as effectual as opaque ones in arresting the heat of the fire; but this is not so; the most intense artificial heat and light is probably that produced by charcoal ignited by voltaic electricity, and when a small lens is placed before a brilliant star of fire so obtained, and its focus thrown upon an air-thermometer, an elevation of temperature is always indicated. (Brande, *Phil. Trans.*, 1820.) Mr. Daniell has shown a similar effect in the rays from incandescent lime. (*Phil. Mag. N. S.*, ii. 59.)

There are other well known instances, in which the passage of common radiant heat through glass is evident; if we stand, for instance, upon the outside of a shop-window when a gas-burner within is suddenly lighted, we perceive the instantaneous impulse of heat upon the face; and there is no difficulty in causing radiant heat, even of low intensity, to permeate glass and other transparent media in very thin layers. It was supposed that in these cases the direct transmission of the radiant heat was apparent only, and that it, in fact, was absorbed by, and heated the glass, which therefore itself became the radiating surface; an objection ingeniously answered by Prevost, who transmitted the heat of a flame through a thin sheet of water, issuing from a jet, so that the nature of the medium, as well as its constant motion, prevented all possibility of the transfer of the heat by any other method than direct radiation.

Newton conceived that radiant matter consisted of *particles* emanating from luminous and heated bodies with prodigious velocity; these particles he imagined might be of different sizes; the smallest, constituting chemical rays and violet light, being the most refrangible; the larger ones forming red light and heat, and being the least refrangible; and some have assumed that the matter emanating from terrestrial bodies might be so constituted as to be arrested by those transparent media

which allow a ready passage to solar rays. Newton put the query, "Whether light and common matter are not convertible into each other?" And, if we consider sensible heat in bodies to depend upon vibrations of their particles, a certain intensity of vibrations may send off particles into free space; and particles moving rapidly in right lines, may in losing their own motion, communicate a vibratory motion to the particles of terrestrial bodies."—(DAVY'S *Elements*, p. 215.) The explanation of the phenomena of radiant heat upon the undulatory theory, will be evident from what has been above stated.

But our knowledge respecting the transmission of heat through different media has been lately much extended by the profound and important researches of Melloni. (TAYLOR'S *Scientific Memoirs*, i. and iii.) He has shown that heat which has passed through one plate of glass becomes less susceptible of absorption in passing through a second. Thus, of 1000 rays of heat from the flame of oil, 451 were intercepted in passing through four plates of glass of equal thickness, of which 381 were intercepted by the first plate, 43 by the second, 18 by the third, and 9 by the fourth. But the most remarkable of Melloni's discoveries is that of the transmission of radiant heat through certain transparent bodies almost without impediment, while others, physically analogous, resist its passage; nor is this passage of heat dependant upon their transparency in regard to light: the latter are *diaphanous*, the former *diathermanous*. Thus, plates of the following transparent substances, each being 0.1031 of an inch in thickness, allowed very different portions of the rays of heat from an argand lamp to traverse them. Of 100 incident rays,

Rock salt	transmitted	92	Emerald	transmitted	29
Mirror glass	"	62	Gypsum	"	20
Rock crystal	"	62	Fluor spar	"	15
Iceland spar	"	62	Citric acid	"	15
Brown rock crystal	"	57	Rochelle salt	"	12
Carbonate of lead	"	52	Alum	"	12
Sulphate of baryta	"	33	Sulphate of copper	"	0

A slice of brown rock crystal, nearly opaque in regard to light, and 58 times thicker than a transparent plate of alum, transmitted 19 rays, while the alum only transmitted 6.

Melloni found the proportion of heat from different sources, which passes through a plate of glass 1-50th of an inch in thickness, to be as follows:—

	Transmitted.	Absorbed.
Of 100 rays from the flame of an oil lamp	54	46
" Red-hot platinum	37	63
" Blackened copper heated to 732°	12	88
" Ditto ditto to 212°	0	100

Rock salt is the only substance whose powers of transmission are the same for heat from all sources and all intensities, 92 per cent. of the incident heat passing through that substance, whether radiating from a bright flame or from the hand: sulphate of copper, on the contrary,

notwithstanding its transparency as regards light, is *athermanous*, or opaque, as regards heat.

It appears probable that these remarkable differences are rather the result of mechanical structure than of chemical composition, for when a block of common salt is divided into flakes, it arrests calorific radiation. The extraordinary properties of rock salt in regard to radiant heat render it invaluable in these researches; it constitutes "the true glass of radiant heat," and may be cut into lenses and prisms, and used for concentrating heat of all intensities, and decomposing it by double refraction, exactly as glass is in regard to solar rays.

Of 100 rays of heat from the same source, successively incident on water, alcohol, ether, bisulphuret of carbon, and chloride of sulphur, the transmitted rays were 11, 15, 21, 63, and 63. The rays transmitted through similar plates of coloured glass, were with violet glass 53, with red 47, with yellow 34, with blue 33, and with green 26.

It would further appear from Melloni's experiments, that as there are varieties of light characterized by different colours, so there are different kinds of radiant heat dependent upon the sources whence it emanates. Rays of light which have passed through blue glass, will pass more readily through a second blue glass than through one of a different colour; and calorific rays which have passed through water, will pass more readily through a second stratum of water than through other liquids otherwise more diathermanous. Hence it follows that comparatively little additional heat is absorbed either by increasing the number or thickness of screens of the same material.

Having stated these facts concerning the receptive and transmitting powers of bodies in regard to radiant heat, we may now turn our attention to their emissive energies, and we shall find, that those bodies which have their temperatures most easily raised by the action of rays producing heat, are likewise those which are most easily cooled by their own radiation; or which, at the same temperature, emit most calorific rays; in other words, the *receptive* and *emissive* powers of surfaces, in regard to radiant heat, are co-existent and co-equal.

From what is stated above, it will appear that, if we place two similar metallic vessels filled with water before the fire, the surface of one of the vessels being clean and polished, and that of the other covered with a thin coat of lampblack, the former will receive heat much more slowly than the latter: a blackened saucepan set near a clear fire has its contents much sooner heated than a clean and bright one in the same situation.

Let us now reverse the experiment, and fill the blackened and the polished vessel respectively with hot water, and putting a thermometer into each, leave them upon a table at a distance from each other, and not near the fire. We shall soon observe that the thermometer falls most rapidly in the blackened vessel, and that it becomes cool much sooner than the other. Perhaps a simpler way of showing this fact, consists in painting one-half of the surface of a convenient tin or pewter vessel with a mixture of lampblack and gum-water, and leaving the other half or side clean and polished; if it then be filled with boiling water, no very delicate instrument is requisite to prove that heat is thrown off much more quickly from the unmetallic than from the metallic sur-

face; for the hand brought near the former feels a much greater impression of heat than when at an equal distance from the latter.

If we paste writing-paper, linen, or thin woollen cloth, or flannel, upon one half or side of a canister, and leave the other side clean, a very similar effect will be observed, for those surfaces radiate much more than metals; and, accordingly, a differential thermometer brought near a canister so prepared, will be affected at a much greater distance by the covered than by the clean surface.

The mutual relation of the receptive and emissive powers of bodies in regard to radiant heat, is well shown by a form of experiment devised by the late Professor Ritchie (*R. S. Journal*, v. 305). For the glass bulbs of a differential thermometer he substituted two hollow discs of thin metal plate: the surface of one of these discs was bright, and of the other coated with lampblack. Between these discs he placed a similar one filled with hot water, of which also one of the surfaces was bright and the other coated: when the heated disc was so placed between the thermometric discs that the blackened surface of the one opposed the metallic surface of the other, and *vice versâ*, no effect was produced upon the thermometer; but when the similar surfaces were opposed, namely, black to black, and metal to metal, the thermometer immediately indicated a great access of heat. In the first position the respective actions of the surfaces exactly balanced each other: in the second the good radiator was opposed to the good receiver, and the two bright surfaces to each other, so that everything favoured the effect on one side and opposed it on the other, and hence the great effect upon the thermometer.

It will be observed that these effects of radiation are singularly opposed to the *conducting* powers of the respective surfaces. If we touch the clean part of the canister it burns us; but we may place the finger with impunity upon the paper or flannel, which, though a good *radiator*, is a comparatively bad *conductor* of heat.

The following table of the comparative radiating powers of different substances, is drawn up from Leslie's experiments:—

Lampblack	100	Tarnished lead	45
Sealing-wax	95	Clean lead	19
Writing-paper	98	Polished iron	15
Crown glass	90	Tin plate)	
China ink	88	Gold	Polished . . . 12
Red-lead	80	Silver	
Isinglass	80	Copper)	
Plumbago	75		

It appears therefore that those surfaces which are not metallic, such as soot, paper, glass, &c., are much better radiators of heat than tarnished metals, lead, or iron; and that these latter radiate better than the polished metals, which consequently stand at the bottom of the list. It will also be recollected that the above numbers represent the *receptive* as well as the radiating powers of the respective surfaces. In regard to roughened metallic surfaces, Leslie found their radiating powers much dependent upon the manner in which they had been scratched; when a number of lines were scratched in one direction upon a bright metal, the force of ra-

diation was increased: he then drew the same number of lines, but so that they crossed each other at right angles, and a still greater radiant power was obtained; as if it depended upon the number of points produced.

The different radiating powers of metallic surfaces is stated by Melloni to be connected with differences in their densities. He formed two silver vessels, one of well hammered plate, the other of cast and slowly cooled metal; one side of each was highly polished, and the other scratched with emery-paper in one direction only. On filling them with hot water, he found the following differences:—

Hammered metal polished	= 10°	Cast metal, polished	= 13°·7
Ditto scratched	= 18°	Ditto, scratched	= 11°·3

The polished surface, therefore, of the cast metal, radiated much better than that of the forged, showing the superiority of inferior density; but with the scratched surfaces, the radiation is in favour of the hammered or denser metal, an effect which Melloni refers to the compression of its surface by the friction of the emery.

Let us now look at some of the economical applications of the facts arising out of the philosophy of radiation.

Before much was known respecting the radiating, and consequent cooling power of different surfaces, it was presumed that vessels of earthenware or porcelain were better calculated to retain heat, than those of metal; it was rightly argued, that the latter were by far the best *conductors* of heat, and it was inferred, therefore, that they would lose heat to the surrounding air more rapidly than bad conductors. Experienced tea-makers, however, always maintained that the best tea was made in a bright silver vessel, and that earthen teapots were of far inferior power; the former were said to *draw* much better than the latter. This opinion we now know is correct, and the obvious reason for the preference is, that the water retains its heat longer in the metal than in the porcelain vessel, and consequently extracts the soluble matter of the tea-leaves more completely.

“Vessels,” says Sir H. Davy, “that are intended to *retain* their heat, should be metallic, and highly polished; and, independent of elegance and delicacy, there is a reason, obvious from the preceding facts, why metallic vessels for the purposes of the table should be kept as bright as possible. Steam or air pipes for warming houses, should be polished in those parts where the heat is not required to be communicated, and covered with some radiating substance, such as lampblack or plumbago, in those rooms which are to be heated by them. Culinary implements should be blackened, and not polished, on those parts which are to *receive* heat. The heated surfaces of fire-places or stoves should not be metallic, but of stony or earthy materials; and in this case, much more heat will be communicated by radiation.”

It is also obvious, that whenever radiant heat is to be absorbed, rough, unmetallic surfaces should be employed; and these, in the case of solar rays, may be blackened, in order to render the heat more intense. Brick-walls are excellent absorbers and radiators of heat, and when exposed to the sun's rays they become very hot; afterwards, when the sun goes off, they again radiate the heat which they had previously received, and which

caused their excess of temperature over the surrounding bodies. Walls against which fruit-trees are planted are sometimes painted black, in order to get the highest possible degree of heat during their exposure to the sun; but it is not found that the fruit is thus improved.

The way in which we receive heat from our ordinary fire-places will now be intelligible, and it will be evident that it is principally by *radiation*, the hot and dilated air making its escape up the chimney, attended by an enormous waste of heat, and consequently also of fuel. The heat which radiates from the glowing coals, and from the heated surfaces about the grate, is projected into the chamber, traversing the air without heating it, and impinging upon the different bodies around, is received by them with different degrees of facility, dependent upon the nature of their surfaces: the carpet, and all similar surfaces, absorb the radiant heat with facility; furniture and wooden articles become also heated; and these radiate in their turn, and throw off their excess of heat above that of surrounding bodies. They also warm and dilate the air in contact with them, and thus the heat becomes more or less equally diffused throughout the chamber. Our clothes are also, in general, good absorbers of heat; so is the skin or cuticle; and by the absorption of the radiant heat we get warm on standing before the fire, at least upon that side or part which is exposed to it. This partial reception of heat by which we are burned on one side, while the other may be very cold, is one of the great objections to our common mode of warming apartments; and another is, that in winter, one part of the room only is comfortable, whilst others are disagreeably cold. In rooms heated by throwing into them a current of warm air, such inconveniences are not experienced; but then, unless there is at the same time a thorough ventilation, they produce a sensation of closeness which is unpleasant to those accustomed to open chimneys and fires. A combination of the two systems is the most efficacious and pleasant; warm air, properly and judiciously admitted at the parts of the room furthest from the fire; and an open grate, to assist in warming, and to accomplish a perfect ventilation. Grates or stoves have lately been contrived in which there is an open fire as usual, and which also throw out a stream of warm air, heated by being made to pass from below upwards through a double casing, surrounding all the heated parts of the grate; these stoves, when properly made and applied, are extremely effective and economical.

But it is seldom recollected that all attempts to render any individual apartment in a house uniformly warm, will be frustrated, unless the mass of air in the halls and staircases is also heated; this is most effectually accomplished by a properly-constructed stove upon the basement story, and although the expense of such an arrangement is considerable at first, it will be found, if properly and judiciously made, to effect a material annual saving in fuel. Dr. Arnott's stoves are also excellently adapted to all these purposes. Whilst upon this subject I may be allowed to remark, that it is to be regretted that architects and builders in general are extremely inattentive to the methods of warming and ventilation, both as concerns dwelling-houses and public edifices.

From what has been elsewhere stated respecting the conducting and carrying powers of bodies, in respect to heat, and from the phenomena

of radiation, it is obvious that when a body is allowed to cool in the air, its heat will be carried away, first, by the absolute conducting power of the medium; secondly, by currents established in it, in consequence of change of density; and thirdly, by radiation; and that the separate influence of each of these causes must be considered. Supposing, however, a body to be placed in a *perfect vacuum*, its heat would be dissipated by radiation only; to determine, under these circumstances, the rate of cooling, an elaborate inquiry has been undertaken by MM. Dulong and Petit (*Ann. de Chim. et Phys.*, vii.); but the details rather belong to physical than chemical science. It appears that bodies cool about twice as fast in the air as in vacuo: Dr. Franklin conceived that a body requiring five minutes in vacuo, would cool through the same number of degrees in air in two minutes. Count Rumford gives the proportions of five minutes and three. But the rate of cooling will much depend upon the relative temperature of the body, and it will lose unequal quantities of heat in equal times, forming, according to Newton, a decreasing geometrical progression. Thus, supposing the temperature of a body to be 1000° above the surrounding medium, and that it were to lose 100° of heat in the first minute, it would lose 1-10th of the remaining 900° in the second minute, (or 90°), and 1-10th of the residual 810° (or 81°) during the third minute, and so on; so that the number of degrees lost during the first five minutes, would be 100, 90, 81, 72.9, and 65.6. This law of cooling, however, though perhaps tolerably correct at low temperatures, becomes liable to much error at high ones, the error increasing as the temperature augments.

In relation to this subject, the following summary is given by Dr. Thomson, founded upon the researches of Dulong and Petit.

1. "When a body cools in a vacuum, the heat which it loses is entirely by radiation. When it cools in air, the process goes on more rapidly, because the quantity of heat radiated is the same as in vacuo, while an additional quantity of heat is conducted away by the air. 2. The rate of cooling of a liquid is not altered by the size or shape of the vessel. 3. The velocity of cooling of a thermometer in vacuo, for a constant excess of temperature, increases in a geometrical progression, when the temperature of the surrounding medium increases in an arithmetical progression. The ratio of this geometrical progression is the same, whatever be the excess of temperature considered. The truth of this law will be evident from the following table:—

Excess of temp. of the therm. centigr.	Velocity of cooling Water at 0° .	Ditto Water at 20° .	Ditto Water at 40° .	Ditto Water at 60° .	Ditto Water at 80° .
240°	10.69	12.40	14.35	—	—
220	8.31	10.41	11.98	—	—
200	7.40	8.58	10.01	11.64	13.45
180	6.10	7.04	8.20	9.55	11.05
160	4.89	5.67	6.61	7.68	8.95
140	3.88	4.57	5.32	6.14	7.19
100	3.02	3.56	4.15	4.84	5.64
120	2.30	2.74	3.16	3.68	4.29
80	1.74	1.99	2.30	2.73	3.18
60	—	1.40	1.62	1.88	2.17

"If we compare the five last columns of this table with each other, we shall find that the mean ratio is 1.161. In general, this geometrical progression requires to be diminished by a constant quantity, in consequence of the heat radiated back to the hot body from the walls of the vessel in which it is cooling. 4. When a body cools in vacuo, the time of cooling is materially influenced by the nature of the surface of the hot body; those bodies cooling soonest which radiate best. But this difference does not affect the law of cooling in vacuo. 5. When a body cools in any gas, the same portion of its heat is carried off by radiation that would be dissipated if it were cooling in a vacuum. Another portion is conducted off by the gas. This last portion is not affected by the nature of the surface of the hot body. It depends upon the conducting power of the different gases. 6. The celerity with which heat is communicated from hotter bodies to colder ones, when all other things are equal, is proportional to the extent of contact and closeness of communication between the bodies."—(Outline &c., § IV.)

§ 18.—PHOSPHORESCENCE.

THIS term is generally applied to those bodies which shine in the dark, without undergoing combustion, though, in some cases, a low form of combustion goes on at common temperatures, or when substances are only slightly heated, which has occasionally been confounded with the luminosity of phosphorescence.—(See a report upon this subject, by Dr. C. Williams, in the *Proceedings of the British Association*, iv. 588.) The products of *combustion* (properly so called), at different temperatures, will be noticed in the sequel. The varieties of *phosphorescence* may be considered under the following heads:—

1. Bodies which become luminous after having been exposed to light, and which are generally called *solar phosphori*.
2. Bodies which become luminous when moderately heated.
3. Bodies of vegetable and animal origin, which are spontaneously luminous at common temperatures.

1. SOLAR PHOSPHORI.—The attention of philosophers was first drawn to this curious subject, by an accidental discovery of Vincenzo Cascariolo, a shoemaker of Bologna, who (about the year 1630), being engaged in some alchemical experiments, had occasion to calcine a quantity of a species of native *sulphate of baryta*, found near Bologna, at Monte Paterno (*AIKIN'S Dictionary*, Art. PHOSPHORI). He observed that, whenever the spar had been sufficiently heated, it acquired the property of shining in the dark after having been exposed to the sun's rays, and that it would even continue thus to emit light for some hours. In consequence of this discovery, the Bolognian spar came into great request among the curious; and the best mode of preparing the *Bolognian phosphorus*, as it was called, became a subject of no small pecuniary importance. The most successful preparers of it were a family of the name of Zagoni, who continued to supply large quantities of it to the curious throughout Europe, and retained their monopoly for many years. Their process is not exactly known; but if the spar be powdered, and made into thin cakes, with mucilage of gum tragacanth, and then carefully calcined

in the open fire, and suffered to cool slowly, they will be found to answer the purpose: that is, they will glow for some time in a dark room, after having been exposed to a bright sunshine. Some management, which can only be learned by practice, is requisite in conducting the calcination. Any variety of sulphate of baryta will answer for the above preparation, but that which is massive, nearly opaque, and of a lamellar fracture, appears, on the whole, to furnish the most luminous product.

There are many other substances possessed of properties analogous to those just described. For the discovery of one of these we are indebted to Canton, by whose name it is usually known. *Canton's phosphorus* is made by calcining oyster-shells in the open fire for half an hour; after which the whitest and largest pieces are selected, mixed with about one-third their weight of flowers of sulphur, pressed into a crucible with a closely luted cover, and heated red-hot for an hour. When the crucible has become quite cold, turn out its contents, and select the whitest pieces for use.

For the following solar phosphorus, we are indebted to Mr. B. Wilson (*On Phosphori*, p. 20):—"Select a score of oyster-shells, the thicker they are the better; then take most of the flaming coals, but not all of them, off a fire that is burning briskly, strew the shells over the surface, and replace the coals that have been taken off. In about an hour's time take out the calcined shells, observing to break them as little as possible; and after exposing them for a few minutes to the light, they will be found to have acquired a high degree of phosphorescence, glowing in the dark in a very beautiful manner, with most of the prismatic colours. It is not, however, absolutely necessary that the shells should be calcined in the open fire, for if they are heated sufficiently in a close crucible, they will exhibit prismatic colours, chiefly blue and green, though not so bright as by the former method. If the calcination is effected in an iron crucible, all those parts of the shells that have been in contact with the sides of the crucible will glow with a red light. The contact of inflammable matter, and particularly charcoal, with the shells during their calcination, appears eminently to contribute to the brilliancy of the phosphorus. Hence it is that if the shells are calcined in a crucible, in contact with thin plates of steel, (steel being a compound of iron and charcoal,) the phosphorus thus produced will be much more bright, and of more various colours than when plates of iron are employed; and, on the other hand, if flat pieces of charcoal are made use of, the intensity of the colours, especially of the blue, green, and red, is far greater than in those produced by the steel."

Another solar phosphorus is that discovered by Baldwin. It is made by saturating diluted nitric acid with chalk, and evaporating to dryness, by which a *nitrate of lime* is obtained. This, when melted at a dull red heat, cools into a compact mass, which has the property of imbibing and emitting light.

It has been observed, in regard to these *solar phosphori* in general, that their luminous power is diminished by cold and increased by heat; that they are more brilliant in dry and warm than in wet and cold weather; that they shine most intensely after exposure to direct sunshine; but that some of them, especially the oyster-shells, exhibit their

phosphorescence when carried into a dark place, after mere exposure to ordinary daylight. It is sometimes said, that they absorb the same coloured light as that to which they are exposed, and that, if exposed to red light, they give out red, to green, green light, and so on; but this appears to be a mistake, the colours of the light being white or reddish white, and often prismatic, but independent of the colours of the rays to which they have been exposed. Moonlight is quite inadequate to render these bodies luminous; but the flash of gunpowder, the light of a bright candle or lamp, or of an electric explosion, suffices to make them shine more or less intensely.

The above are the most remarkable solar phosphori, but there are several other substances possessed of very similar properties, such as some diamonds, rock-crystal with its surface roughened, certain saline bodies, and writing-paper: these, however, are less powerfully luminous, and require good management to be observed. They should be brought out of the light to the observer, who should be stationed in a small closet, painted black on the inside, and with a black curtain hung up before the door. (BECCARIA, *Acta Bologn.*, 1744—1747, and *Phil. Trans.*, Lxi. 212. See also HEINRICH, *Bib. Univ.*, xv. 247.)

2. PHOSPHORI FROM HEAT.—There are many substances which become luminous when moderately heated; that is, at a temperature below a red heat. These differ from the preceding in the circumstance, that, after having been kept at any particular temperature till their luminousness is exhausted, they are incapable of shining again, except at a temperature greater than that to which they were first subjected. The substances belonging to this class are extremely numerous, and an extended series of experiments upon them, by Sir D. Brewster, will be found in the *Edinburgh Philosophical Journal*, I.; but there are only a few which are eminently luminous; of these the compact *phosphate of lime*, found native near Estramadura, in Spain; and certain kinds of *fluor*, or Derbyshire spar, especially the dark blue and slightly fetid variety, are the most remarkable: the former exhibits a beautiful pale-green light, intense enough to be seen in the daytime; and the latter shines with a purple tint; a variety termed, from its shining with a green light, *Chlorophane*, is particularly brilliant and beautiful. The best way of exhibiting them is to heat them in a dark room, in a spoon of platinum, over a spirit-lamp, the light of which is not sufficient materially to interfere with the observance of their phosphorescence. They should be in small fragments, but not too finely powdered. The *fetid carbonate of lime*, called *swinestone*, not uncommon near Bristol, several varieties of *calcareous spar*, and of *heavy spar*, and *powdered quartz*, are substances which are also luminous when heated; they may be strewed for this purpose upon a piece of iron which has been heated red-hot, and just ceased to glow. Mr. Pearsall has shown that, after the luminosity of many of these substances has been destroyed by heat, it may be restored to a certain extent by electrical discharges; and that electricity generally exalts the power, and in some cases confers it where it did not previously exist. Several other curious facts, in reference to this subject, will be found in his papers. (*Roy. Inst. Jour.*, i. 77 and 267.)

The substances which are phosphorescent by heat are also generally

so by *friction*, which is another productive source of luminosity. There are also several bodies which are rendered luminous by passing an electric shock through or over them; such, for instance, as a lump of loaf-sugar, which shines for several seconds afterwards with a beautiful blue light. (SKRIMSHIRE in *Nicholson's Jour.*, xv., xvi., and xix.)

3. SPONTANEOUSLY PHOSPHORESCENT SUBSTANCES.—Under this head we may place a variety of *animal substances* which, under certain circumstances, emit light. The flesh of certain fresh and salt water fish becomes luminous previously to its putrefaction; of these the tench and carp, and the herring and sole, are perhaps the most remarkable; the fish should be gutted and split, and the scales scraped off; if placed in a dark cellar, they are then often observed to shine within twelve or twenty-four hours, the time depending upon the temperature and state of the atmosphere, and probably other causes which have not been determined: this appearance ensues before any bad odour is perceptibly exhaled; and soles are often luminous in the dark, when perfectly fit for the table. Lobsters and crabs, under similar circumstances, are often very rich in phosphorescent matter. It appears, from the experiments of Canton and of Dr. Hulme (*Phil. Trans.*, vols. lix., xc., and xci.), that sea-fish become luminous in about twelve hours after death, that it increases till putrefaction is evident, and that it then decreases. Immersion in sea-water does not effect this luminous matter; on the contrary, the brine is itself rendered luminous: but it is extinguished by pure water, and by a variety of substances which act chemically upon the animal matter. The ligamentous parts are more luminous than muscular fibre; especially the eyes. Phosphorescence is rarely observed in the flesh of quadrupeds, and never in that of birds, under any circumstances of decomposition.

There are many *living animals* which have various powers of emitting light. One of these is the *glow-worm*; and there are others which, under certain circumstances, are powerfully phosphorescent. The common *hundred-legged worm*, found under bricks and pots in the garden, exhibits brilliant flashes of light when irritated. The *lantern* and *fire-flies* of warmer climates are also remarkable for their emission of light.

Dr. Macculloch, in his work on the Western Islands of Scotland, and in a paper published in the *Quarterly Journal* (xi. 249), has detailed some valuable facts respecting that beautiful appearance of light in sea-water, so well known to those who are conversant with the ocean during the darkness of night; he has shown that the sea is often crowded with worms and insects nearly invisible, and that its luminous property not only bears a relation to the existence and number of these at any time, but may generally be traced to the individuals by which it is caused. One of these luminous animals, described by Captain Home, is figured in the *Quarterly Journal*. N. S., vol. iv., p. 383.

In the *vegetable world* phosphorescence is a less common quality. *Decayed wood*, and occasionally *peat*, have been observed to emit a faint light; and there are a few flowers, among which may be mentioned the *tuberose*, *nasturtium*, and *marigold* (*Tropæolum majus*, and *Calendula vulgaris*), which have occasionally been observed to give out brilliant flashes upon a warm summer's evening. The leaves of the *Phytolacca decandra*, have also been seen to emit light, and a similar appearance

is mentioned by Mr. Mornay, peculiar to the sap of a Brazilian *Euphorbia*. There are certain mosses too, which occasionally phosphoresce; and some species of *Rhizomorpha* have been observed to be luminous in mines.

Certain substances emit light during crystallization: this has been occasionally observed with sulphate of potassa, but the phenomenon, according to H. Rose (*Ann. de. Chem. et Phys.*, lxi. 288), is most distinctly observed during the crystallization of arsenious acid from its solution in hydrochloric acid. About an ounce of the vitreous acid (not the opaque or pulverulous) should be dissolved in three ounces of the acid, diluted by an ounce of water; it should be boiled for about a quarter of an hour, and then suffered to cool very slowly, which is best effected by gradually diminishing the flame of the spirit-lamp used for heating it; in a dark place each crystal that is formed produces a spark of light, and on shaking the flask many crystals are often suddenly deposited, attended by vivid flashes.

We have now enumerated some of the leading cases of what is properly called *phosphorescence*; it appears to consist in an emission of light, independent of ignition or combustion, and referable to a variety of causes, none of which have been very satisfactorily investigated or explained. There are numerous other cases of luminosity referable to changes in the *electric states* of bodies, and which will afterwards be noticed in detail.

§ 19.—EFFECTS OF RADIATION IN NATURE.

THE earth, part of the surface of which is daily exposed to the action of the solar beams, will absorb the rays with various degrees of facility depending upon the nature of the surface; and during the night it will again radiate, or throw off a portion of the heat it has so acquired. It has been ascertained that the extent to which this diminution of temperature takes place, is greatly dependent upon the aspect of the sky; when the night is clear, and the heavens cloudless, it goes on more rapidly, and to a much greater extent, than when the sky is overcast and cloudy; and hence it is, that upon clear nights there is a much greater deposition of dew than in cloudy weather. To understand this, it must be recollected, that *dew* is not a kind of fine rain showering down upon the earth from above, but that it depends upon the deposition of moisture contained in the state of vapour in the air, and is, in its formation, precisely similar to what happens when a glass of iced water is brought into a warm room in summer; the coldness of its surface abstracts the heat from the vapour in the air, and causes its condensation in the form of water, which is deposited exactly like dew upon the outside of the vessel*. So the earth, upon a fine cloudless night, accord-

* This is also the reason why thick and substantial walls in the interior of houses become damp, and often very wet, in certain states and changes of weather. They are so massive as to retain an acquired temperature for a long time, and during a winter's frost become

cold throughout; upon a sudden thaw attended by a very humid state of atmosphere, the vapour or moisture of the air is condensed in the liquid state upon these cold surfaces, because they abstract its heat, and consequently cause it to run down in the form of water.

ing to some, in consequence of the accelerated radiation of its own heat, and to others, in consequence of the radiation of cold from above, becomes colder considerably than the superincumbent atmosphere, and therefore the aqueous vapour, more or less of which is always contained in the air, is condensed in the liquid form upon the surface of the ground; and, of course, most abundantly, upon those parts of the surface, which being the best radiators, or receivers of radiant matter, have their temperatures most depressed. Thus, walking in the garden upon a bright autumnal morning, after a clear night, we observe the dew very unequally deposited: it is commonly most abundant upon the grass-plats, for mown grass is an excellent radiator; it becomes, therefore, colder than the adjacent gravel-walks, upon which the dew is less abundant. If we place a thermometer upon the grass, and another upon the gravel, we shall find the former sink several degrees below the latter; and under circumstances favourable to the deposition of the dew, the earth's surface will always be found colder than the air above it. A thermometer on the grass has been observed, under favourable circumstances, to fall as much as from twenty to thirty degrees below one suspended some feet above it. The consequence is, that the lower strata of the atmosphere in contact with the cold surface of the earth, are considerably colder than the higher parts; and if the air is tranquil, will remain so for some time, especially in *hollows*, and other places protected from currents, and where the warm and the cold air are not therefore mixed by mechanical agitation. Hence it is that delicate plants often suffer more in situations apparently protected, than in those which are open and exposed, and where the cold air has not such a chance of lying quiet upon the surface.

All *good radiators*, exposed upon the earth's surface, will become *colder* than bad ones; if, therefore, we place upon an exposed gravel-walk a piece of flannel and a piece of tin-foil, the former will have abundance of dew thrown down upon it, and the latter none; and, in reference to this fact, it is curious to observe the influence of the natural textures and surfaces of foliage. Smooth, varnished leaves, have no dew deposited upon them, under circumstances in which there is an abundant deposition upon rough and downy leaves; the former, therefore, seldom suffer from this cause of cold, but the latter are often frost-nipped.

The remarkable influence of clouds in preventing radiation, seems first to have been noticed by Dr. Wells, whose *Essay on Dew* deserves the attentive perusal of all who are interested in this part of meteorology. He found that, if the night, at first clear, becomes cloudy, the temperature of the grass always rises, independent of any changes of calmness, and nearly so of change of atmospheric temperature. Upon one such night the grass, after having been *twelve* degrees colder than the air, became only *two* degrees colder, the temperature of the atmosphere remaining stationary; and, on another occasion, the temperature of the grass rose *fifteen* degrees, while the air only sustained an increase of *three and a half*. Any protection interposed between the earth and sky, prevents radiation, in the same way as a cloud. If we place four poles in the ground, and stretch a mat or canvass upon them, the plot underneath will be effectually preserved from those changes of temperature referable to the escape of radiant heat from the surface, or, to the reception of radiant

cold from above. In this way gardeners protect young and tender plants; though it is obvious that any general changes, dependent merely upon atmospheric temperature, would not be interfered with, nor the cold kept off by such a contrivance.

Radiation, therefore, is constantly going on from the earth towards the regions above. If we place the bulb of a delicate thermometer, especially if it be covered with some good radiating substance, in the focus of a concave metallic mirror turned towards the clear sky, it will indicate cold: this was referred by Leslie to radiation of cold from the regions of space; and thus he employed a differential air-thermometer in the construction of his *Æthrioscope* (See *Encyc. Brit.*, Art. CLIMATE,) to indicate, as he terms it, "*cold pulses emanating from the sky*," or, as others have expressed it, to give a comparative idea of radiation proceeding from the surface of the earth towards the region of perpetual congelation in the atmosphere. "The thermometer is protected by its position from the radiation of surrounding objects, and its own radiant heat is projected towards the clear space, or falling upon the concave surface of the mirror, is reflected in parallel lines in the same direction. This effect is produced even while the sun is above the horizon, provided the mirror be turned from the direct rays of that luminary; and at night a depression of 17° below the temperature of the air and surrounding objects may commonly be produced. Perfect stillness of the atmosphere is necessary, and perfect transparency also, for otherwise the balance of temperature is soon restored by convection, and the slightest mist destroys the effect by a counter-radiation." DANIELL, § 275.

In the eighty-third volume of the *Philosophical Transactions*, Mr. Williams has described the mode of obtaining ice in Bengal, where the atmospheric temperature never falls to the freezing-point. It is evidently chiefly effected by radiation from the surface of shallow pans of water (and water is an excellent radiator), which are placed upon dry stubble in open situations: calm, serene, and cloudless nights are most favourable to the purpose; and thin crusts of ice are thus frequently obtained. In such cases the production of cold has sometimes been referred to evaporation, but that this is not the cause of the diminution of temperature, in the present instance, is proved by the peculiar circumstances requisite for the success of the operation being entirely independent of it.

§ 20.—OF IGNITION AND COMBUSTION.

It will be evident, from the contents of the few preceding pages, that there is a connexion between light and heat, and that they are mutually disposed to produce each other; indeed, they are probably convertible into each other; but these, and other mysterious relations between them are as yet very imperfectly understood.

In the mean time it may be right to mention a supposed exception to the relationship between heat and light, furnished by an examination of the *lunar rays*, which, though concentrated by the most powerful lenses, are incapable of affecting very delicate thermometers. De la Hire collected the rays of the full moon when in the meridian, by a lens thirty-five inches in diameter, and threw them upon the bulb of a very sensible

air-thermometer, but they produced no effect, though they were thus concentrated 306 times. It is not, however, surprising that the moon-beam should be thus inefficient, when we consider the extreme feebleness of its illuminating power, as compared with a solar ray of the same size; the light of the latter being at least 300,000 times greater than that of the former. It appears probable, therefore, that the properties of the moon-beam are to be referred to its *feebleness*, as compared with that of the sun, though there may be some peculiarity in its nature, or some power in the surface of the moon of retaining the heat, whilst it emits the light received from the sun. It has even been supposed that the moon may radiate cold.

By the terms *ignition*, and *incandescence*, we express a property which bodies possess of giving out light, whenever their temperatures are raised up to a certain high point. The quantity of light thus emitted increases with their temperature: at first it is dim and feeble; then it becomes dingy red, and the bodies are said to be *red-hot*; then bright red, commonly called a *cherry-red* heat; then, as the temperature increases, the body becomes of an *orange* or yellow tint, and at length acquires such brilliancy as to be painful to the eye; the latter is usually termed *white heat*.

Various experiments have been instituted to determine the temperature at which bodies become visibly red-hot; this, in a dark place, certainly exceeds six hundred and sixty degrees of Fahrenheit's scale, for at that temperature mercury boils, and it is not, in the least degree, luminous. Sir H. Davy's experiments place the degree of incipient luminosity in a dark place at about 810° . A dull red, visible in daylight, is probably equal to about 1000° , a full red heat to 1200° , an *orange heat* to 1700° , and a white heat to 3000° .

These observations of course only apply to bodies capable of sustaining high temperatures without changing their state, or undergoing decomposition, most substances being either dissipated or destroyed before they attain the requisite temperature for ignition; or, if heated in the air, *inflaming* and undergoing *combustion*.

In all the ordinary cases of combustion air is present, and the phenomena presented by the burning body are referable to the chemical action which ensues, at high temperatures, between it and one of the component parts of the air, called *oxygen*, which, being invisible, long escaped observation as an important agent in the process, and of which we shall have to speak at length hereafter.

The *temperatures* at which bodies burn or inflame in the air are extremely various; some take fire under all circumstances the moment they are exposed to it; others require their temperatures to be more or less elevated; and some refuse to burn under any circumstances. Thus we speak of *combustible* and *incombustible*, or *inflammable* and *uninflammable* bodies; and we call the oxygen of the atmosphere, and such other bodies as are possessed of similar powers, *supporters of combustion*. All common cases of combustion, then, taking place in the atmosphere, depend upon the union of the combustible with oxygen; between these bodies there necessarily exists a strong chemical attraction, and of this, one of the results is the *evolution of heat and light*.

The result of the union of the combustible with the supporter, is called the *product of combustion*; it is very commonly gas or vapour, and eludes ordinary observation: thus, the immense quantity of coal daily consumed as common fuel, combines with the oxygen of the air, and forms several products, of which the principal are *carbonic acid gas* and *steam*; and these pass off by the chimney, and are dissipated in an invisible state through the immense mass of the atmosphere. The *incombustible* earthy matter contained in the coal resists combustion, and forms *ashes*; or, mixing with a part of the coal, renders it difficult of combustion, as we see in *cinders*.

But the product of combustion is often a *solid* body; thus, if we throw a piece of the metal *zinc* into the fire, or heat it red-hot in a crucible, it burns with a very vivid flame, and a quantity of a solid white substance is produced, which is a compound of the metal and the oxygen of the air, and is, therefore, called *oxide of zinc*.

Nothing is more common than to speak of the *destruction* of bodies by combustion; but the term is in so far improper, inasmuch as *matter is indestructible*; and when we seem to destroy a coal by burning it, we, in fact, only cause it to enter into new combinations; and the carbon which it chiefly consists of, although it apparently disappears, has only entered into a new combination, which may be found escaping from the chimney in the invisible state of air or gas, but from which the solid carbon may again be obtained by certain chemical operations.

Such are the general results of combustion: they have here been adverted to in order to explain the nature of *flame*, a subject which has been studied with much attention and curious results by several eminent chemists.

It has often been doubted whether pure gaseous matter is, under any circumstances, susceptible of becoming luminous; certain it is, that its temperature may be elevated far beyond that which is required to ignite solid bodies, and it yet remains invisible. By passing air over heated surfaces, its temperature has been so far elevated as to render metallic wires red-hot, yet was the air itself not at all luminous. Of this a good instance is afforded by the air that issues from the lamp-glass of an Argand gas-burner, which, though not luminous, will heat a fine wire red, or even white hot, held some inches above it. *Flame*, however, may, in general, be regarded as *luminous gaseous matter*, and its *temperature* is under certain circumstances very intense, even where the *light* which it emits is excessively feeble. Perhaps the purest form of flame which we can exhibit is that of hydrogen gas; its *light* is so feeble as scarcely to be visible in broad daylight; yet its *temperature* is very high, as may be shown by holding a fine platinum wire in it, which immediately becomes *white-hot*: the other metals, under similar circumstances, are generally melted or burned.

Upon what, then, does the *luminosity* of a flame, which renders it valuable as a source of artificial light, depend? *Principally upon solid matter diffused through it, and ignited by it*. In the experiment just cited, the flame of the hydrogen is rendered luminous by the wire; and if we blow any substance through it in fine dust, its brightness will be proportionately increased, though the solid matter be not itself inflam-

mable; as, for instance, if we sift a little lime or magnesia into or through it.

The extent to which the light may be increased is also well illustrated by the ignition of lime in the oxyhydrogen blowpipe, as suggested by Drummond (*Phil. Trans.*, 1826, p. 324), and as since used for the illumination of the solar microscope. That it is the vapour of the lime, raised to this high temperature, that occasions the intensity of the light, is shown by the roof of the lantern being covered by a sublimate of lime. There can be little doubt that the brilliancy of the voltaic discharge between points of charcoal is partly referable also to the formation and ignition of volatilized carbon. There are few instances of a more luminous flame than that of phosphorus, in which the great evolution of light depends upon the ignition of the produced phosphoric acid; and if this acid (forming the smoke of phosphorus) be led by a tube into the flames of alcohol or of hydrogen, it greatly increases their luminosity.

In the flame of tallow, wax, oil, and coal-gas, the brilliancy of the light is chiefly owing to very finely-divided charcoal, which is blended with, and burned in, the flame, and which, if in too large quantity, causes the flame to smoke, as we see especially in ill-made tallow-candles, which, notwithstanding frequent snuffing, throw off a quantity of soot into the surrounding atmosphere, creating a disagreeable suffocating smell, and blackening the walls and ceilings of our apartments*.

Such, then, appears to be the source of the *light* of flames; but there are some other curious particulars respecting their construction, which require more full explanation. In a common candle, the wax or tallow is drawn into the burning wick by capillary attraction, and is there converted into vapour, which ascends in the form of a conical column, and has its temperature sufficiently elevated to cause it to combine with the oxygen of the surrounding atmosphere with a temperature equivalent to a white heat. But this combustion is *superficial* only, the flame being a thin film of white-hot vapour, enclosing an interior portion, which cannot burn for want of oxygen. That this is the case is easily shown, by bringing down a piece of thin glass upon the flame of a candle, so as to cause a transverse section of the flame. We shall then observe a *ring of light* surrounding the interior dark part of the cone (fig. 96,) and the

* For all common purposes of illumination it is essential that the constitution of the light of flames should resemble that of the sun, and, like it, consist of a due admixture of the primary colours; it is seldom, however, that artificial light is perfect in this respect, and accordingly it is not suited to the correct and perfect display of colours, and when viewed through a prism generally shows a predominance of some one tint. The influence of light of *one colour* upon external objects is seen by viewing them through coloured glasses, or more perfectly by illuminating them by a *monochromatic flame*. We obtain an effect of this kind by a lamp fed with spirit

of wine burning in a wick impregnated with common salt, and which, as it produces little else than yellow light, has been called a *monochromatic-lamp*; it shows no perfect colour except yellow, and furnishes a curious analysis of such compound colours as contain yellow by converting them to that tint; all other colours appear very dingy, and nearly black. The brilliant red of cinnabar, as in sealing-wax, and of iodide of mercury appear pale yellow; that of cochineal, as in lake and red morocco, looks black; so also do the brilliant blues of smalt and ultramarine. See Sir D. BREWSTER'S *Letters on Natural Magic*, p. 107.

vertical section of the flame will put on an appearance resembling fig. 97. To prove that *the interior dark part consists of inflammable gaseous matter*, we may insert one end of a small glass tube into the dark central portion of the flame of a large candle, and the interior gas will then make its escape through it, and may be lighted at the other end of the tube, so as to form a second flame. Fig. 98, *a*, shows a section of the flame; *b* the glass tube held in an inclined position in the central part of the flame; *c* the inflammable gas kindled at its extremity.

It is in consequence of this structure of flame that we so materially increase its heat, by propelling a current of air through it by the *blowpipe*, or by supplying its interior with oxygen, as in the gas jet suggested by Mr. Daniell (*Phil. Mag.* 3rd series, II., 57). The perfection of the *Argand burner* is also referable to the same cause.

These peculiarities become more evident in larger flames; so if in a steady atmosphere we inflame some ether or alcohol in a small capsule, we may introduce phosphorus or gunpowder into the centre of it, and they will not be inflamed: a large jet of gas issuing from the top of a lamp glass, may, with a little management, be so inflamed as not to pass down to the orifice of the burner, and it then forms a hollow cone of flame; a small rod of wood, such as a pencil, or a piece of twisted paper, may then be placed across the flame, and it will only be charred or burned at the luminous surface, and not at all affected in the centre. *a* represents the lamp-glass, through which the current of gas is passing; *b* the cone of flame at its mouth; a piece of wood laid across it is singed at *c*; and by the tube, *d*, gas may be drawn out of the interior, and inflamed at its other extremity.

There are several substances which burn at lower temperatures than required for the production of flame. We often see the coals in a common fire glowing at a dull red heat, but not hot enough to inflame the smoke, or inflammable gas and vapour that passes over them, which however may be immediately effected by a piece of flaming paper, or by stirring the fire, which not only accelerates the combustion, but mixes air with the vapour, so as to render it more easily inflamed. The long-continued glowing of the wick of a green wax taper (coloured by verdigris) is another case of combustion, going on at a temperature below that of flame; so is the luminosity of a stick of phosphorus. The phenomena attendant upon such states of combustion are highly curious: when, for instance, spirit of wine is burned *with flame* in the usual way, carbonic acid and water are the products of its combustion; but when burned *without flame*, it pro-

duces acetic acid. The mode of effecting this *slow combustion* is sufficiently simple. A small spiral coil of fine platinum wire is placed upon

100

the wick of a spirit-lamp, and allowed to project about a fourth of an inch above it, as represented in fig. 100. The lamp is then lighted, and suffered to burn for a few seconds, when the flame is put out by an extinguisher, which, however, must be *instantaneously* removed. In this way the coil of wire retains heat enough to carry on the *slow combustion* of the alcoholic vapour, and it continues to glow with a red heat as long as spirit remains in the lamp, and to produce the peculiar acetic product just mentioned: in this way of proceeding, the heat never becomes intense enough to cause the inflammable vapour to burn with flame.

101

There is another, and a very instructive way of making a similar experiment, which consists in pouring a teaspoonful of ether into a tall ale-glass, or small jar of the form represented in fig. 101, and then suspending in it a coil of fine platinum wire, previously heated by holding it for a minute in the flame of a spirit-lamp. The wire being now immersed nearly red-hot into the mixture of atmospheric air and ethereal vapour, *glows with a red heat, causing the slow combustion of the vapour*. It often happens that a part of the wire becomes *white-hot*, and in that case *flame* is produced, and the ether burns with its usual products; but so long as the wire continues only red-hot, no inflammation ensues.

It follows, then, that *flame requires a very high temperature for its existence*; and, consequently, that if we can devise any mode of *cooling* it, it will be *extinguished*. A very small flame, for instance, is extinguished by bringing a large mass of iron near it, or by carefully surrounding it by a coil of wire; the metal abstracts its heat. But by far the most interesting experiments upon this subject are made by help of brass or iron wire-gauze, which may be obtained of different degrees of fineness, and with which the following illustrative experiments are easily shown.

102

103

Procure a piece of this gauze about nine inches square, and of such fineness as to have about thirty meshes in the square inch: bring it gradually down upon the flame of a wax-candle, or, what answers better in all these cases, upon a jet of coal-gas, and the appearances represented in fig. 102 will be produced. The flame will be cut off where it touches the gauze, and we have a good opportunity of observing the exterior luminous circle described above (fig. 96.) In this case the inflammable matter of the flame (in the form of smoke) passes through the wire-gauze; but, in its passage, it is so far *cooled* as to be *extinguished*, and the *flame* is thus prevented from traversing

the wire-gauze. If we now bring a lighted taper above the flame, to the upper side of the wire-gauze, the gas or smoke will be kindled, and the flame continue to burn uninterruptedly, as in fig. 103.

If the meshes of the wire-gauze used in these experiments be not sufficiently small, or if the wire becomes intensely heated, the flame will pass in either instance; because the cooling power is in the one case prevented by the largeness of the apertures, and, in the other, by the high temperature of the wire; or, the wire-gauze may be held in a jet of uninflamed gas, and lighted upon its upper surface, in which case the flame burns there, but cannot descend through the gauze to kindle the gas at the orifice of the burner. This experiment may be curiously varied by placing a small piece of camphor in the centre of a piece of wire-gauze about a foot square, and applying a flame to its *lower* surface. The vapour of the camphor, which is very inflammable, burns with a bright flame upon the lower surface of the gauze, but cannot pass upwards through it, in consequence of its cooling power; so that the camphor itself lies upon the surface of the gauze, in an uninflamed state, though sufficiently heated to furnish inflammable vapour for the sustenance of the flame beneath.

The power of a metallic tissue thus to intercept or extinguish flame will depend upon the heat required to produce the combustion, as compared with that acquired by the tissue; and the flame of the most inflammable substances, and of those that produce most heat in combustion, will pass through a metallic tissue that will intercept the flame of less inflammable substances, or those that produce little heat in combustion: so that different flames will pass through at different degrees of temperature. The cooling power of the wire-gauze is referable to its excellent conducting power for heat; it also, by use, becomes a powerful radiator of heat.

These, and many other interesting investigations connected with the subject of flame, we owe to Sir H. Davy, who most ingeniously applied them in the construction of his *miners' safety-lamp*.

Coal-mines are often infested by a species of inflammable gas (carburetted hydrogen), known under the name of *fire-damp*, which, when mingled in certain proportions with atmospheric air, forms a mixture which explodes upon the contact of flame. Attempts had been made to light such mines so as to avoid explosion, but none were effectual; at length Sir H. Davy constructed a lamp upon the principles explained, which has been used with safety and success.

It is obvious, that if we place a lighted lamp or candle within a perfect cage of wire-gauze, no flame will be able to penetrate *from within* to the surrounding medium, in consequence of the cooling power of the metallic tissue. The annexed figure (104) represents a lamp constructed upon such principles. A is a cylinder of wire-gauze, with a double top, carefully fastened, by doubling over, to the brass rim B, which screws on to the lamp C. The whole is protected and rendered convenient for carrying, by the frame and ring D. If the

cylinder be of twilled wire-gauze, the wire should be at least of the thickness of one-fortieth of an inch, and of iron or copper, and 30 in the warp, and 16 or 18 in the weft to the square inch. If of plain wire-gauze, the wire should not be less than one-sixtieth of an inch in thickness, and from 28 to 30 both warp and woof.—(DAVY *on the Safety-lamp*, p. 114, *et seq.*)

The operation of this lamp may be shown by suspending in it a glass jar, and then admitting a sufficient stream of coal-gas to render the enclosed atmosphere explosive: or, what answers nearly as well, by immersing it into a jar, at the bottom of which is a little ether, and which supplies, by its vapour, an inflammable atmosphere. The flame of the lamp first enlarges, and is then extinguished, the whole of the cage being filled with a lambent blue light; on turning off the supply of gas, or gently blowing the ethereal vapour out of the vessel, this appearance gradually ceases, and the wick becomes rekindled when the atmosphere returns to its natural state.

As the *safety* of these lamps entirely depends upon the perfect state of the wire-gauze, and upon the non-existence of any aperture or channel sufficiently large to admit of the passage of flame, they should, when in use in a coal-mine, be inspected daily. In gas-manufactories, spirit-warehouses, and in all cases where inflammable vapours or gases are likely to be generated, as in the examination of foul sewers and drains, it is obvious that these lamps are importantly applicable*.

* It has been shown, that by throwing a strong jet of coal-gas and air, in explosive proportions, upon the wire-gauze of these lamps, the flame occasionally passes, and this circumstance has been urged as a new experiment, proving the inefficiency of Sir Humphry's safety-lamp: but all practical and unprejudiced experience shows, that when carefully attended to, and used with common caution (which unfortunately is not always the case), they are perfect and efficient safeguards. That Sir Humphry was aware of the possibility of causing the flame to pass is obvious from the following passages of his essay.

"Single iron wire-gauze of the kind used in the common miner's lamp, is impermeable to the flame of all currents of fire-damp, as long as it is not heated above

redness; but if the iron wire be made to burn, of course it can be no longer safe; and though such a circumstance can perhaps never happen in a colliery, yet it ought to be known and guarded against."

"If a workman, having only a common single lamp, finds the temperature of the wire increasing rapidly in an explosive mixture near a blower, he can easily diminish the heat by turning his back upon the current; and keeping it from playing upon the lamp, by means of his clothes or his body; or by bringing the lamp nearer the orifice from which the fire-damp issues, he may extinguish it: and there never can be any occasion for him to place his lamp in the exact point where two currents, one of fresh air and one of fire-damp, meet each other."

CHAPTER III.

CHEMICAL ATTRACTION, OR AFFINITY.

IN a former chapter we have considered *attraction* as disposing the *similar* particles of bodies to adhere, so as to form masses or *aggregates*; and, in many instances, to arrange themselves according to peculiar laws, and to assume regular geometrical figures. We then proceeded to show that *heat*, or *calorific repulsion*, was a power opposed to *aggregation*, tending to separate the particles of matter, and in many ways connected with those extraordinary phenomena which have been referred to *etherial matter*, and under which we were led to speak of *light* and *radiant heat*. We are now to give an outline of the extensive changes which result from certain attractive powers, appertaining to *dissimilar* particles of matter, and sometimes therefore called *heterogeneous*, in opposition to *homogeneous*, *attraction*: they are usually comprehended under the term *chemical affinity*.

§ 1.—GENERAL RESULTS OF CHEMICAL ATTRACTION.

A GOOD instance of *chemical attraction* is afforded by the mutual action of *copper* and *sulphur*. If 16 parts of sulphur broken into small fragments be mixed in a glass flask with 60 parts of copper filings, or turnings, no action ensues; they may be triturated together, but still remain a mere *mixture* of sulphur and copper; but, if heat be applied, so as to fuse and vaporise the sulphur, the copper presently begins to *combine* with it; heat and light are evolved, the copper glowing and burning in the sulphur vapour; and a brittle black compound, quite unlike sulphur or copper, namely, a *sulphuret of copper*, is the result. This simple experiment furnishes the following facts for consideration. First, it shows that mechanical aggregation is opposed in this case to chemical action, and that the sulphur and copper do not combine, till the aggregation of the former is diminished or overcome by heat. 2nd. That chemical action is here attended by the phenomena of combustion. 3rd. That the product has properties essentially different from those of its component parts. 4th. That sulphur and copper combine in certain proportions only; certain definite quantities of sulphur and copper being required to form the *sulphuret*.

We may first observe, that *chemical action is promoted by whatever tends to diminish aggregation or to disintegrate and separate the particles of matter*. In the preceding case, this is effected by *heat*; although it be true, as we shall afterwards find, that *electrical powers* may thus be exalted and called into action. It is this property or effect of heat, that renders it so essential an agent in many chemical operations, both upon the large and small scale.

Another mode of diminishing aggregation, and thereby promoting chemical action, is *solution*, the importance of which, as a prelude to the process of crystallization, has already been noticed (p. 110): its effects are shown by pouring water upon the mixture of tartaric acid and bicarbonate of soda, commonly termed *effervescent* or *sodaic powders*; the materials,

when dry, have no mutual action, but, when dissolved in water, the acid immediately decomposes the carbonate. Hence arose the old, though not perfectly correct, chemical axiom, "*Corpora non agunt nisi sint soluta.*"

But, in many instances, the mere diminution of aggregation by mechanical means, is effective in enabling substances to act chemically upon each other; thus, chlorine has little action upon a lump of metallic antimony, but *powdered* antimony thrown into the gas immediately burns, and produces a *chloride of antimony*: a piece of marble put into dilute hydrochloric acid, is only slowly acted on; but when the surface is increased, and the aggregation overcome by *pulverisation*, it is rapidly decomposed and dissolved. Lead, in its ordinary state, is scarcely acted upon by the air at common temperatures; but if the salt, called *tartrate of lead*, be heated red-hot, in a small tube or phial, the black matter which is obtained contains the *lead in a state of very minute mechanical division*, and in this state it takes fire upon exposure to air. There are some cases of chemical attraction, promoted apparently by peculiar states of the *surfaces* of bodies, which are of an extraordinary nature, and not easily explained: such are the action of certain porous bodies, and of perfectly clean, or finely divided (spongy) platinum upon certain gaseous mixtures: these we shall again refer to.

The evolution of heat and light, attending chemical action, is especially observed where the mutual affinities are intense, or where combination is rapid, and the electrical states of the acting bodies are eminently opposed. That it is not always explicable upon the theory of latent heat, or increase of density, is evident from the numerous cases of an opposite nature in which it occurs, as in the explosion of, for instance, fulminating mercury, and the expansion (attended by decomposition) of the oxide of chlorine. Nor does it appear that any one kind of matter is essential to *combustion*: it is a universal effect of intense chemical action, and proportionate to its rapidity: this is well illustrated in the *slow* and *rapid* combustion of phosphorus; the former exhibits a pale blue light, visible only in the dark, and attended by trifling elevation of temperature; the latter is brilliant in the extreme. When a candle burns, the substances of which it is composed are entering into chemical combination with the oxygen of the surrounding atmosphere; so also with respect to the coals consumed in our fires; and in both cases we observe the combustibles gradually losing their solid form, and acquiring an invisible æriform state; dissolving, as it were, in the air, and disappearing. If we apply a spark to a small heap of gunpowder, it is instantly dissipated in the gaseous form, and a bright flame ensues. In these cases it will always be remembered that there is no *destruction of matter*, but that the charcoal and other substances, composing the candle, the coal, and the gunpowder, have merely entered into new chemical arrangements, and are to be found, as we shall afterwards particularly show, in the *products of combustion*.

The next result of chemical action is, *the production of forms of matter possessed of properties entirely distinct from those of their component parts*, so that it is impossible to anticipate, from our knowledge of the characters of the latter, those which are to belong to the resulting com-

pound: hence chemistry is essentially a science of *experiment*. Oil of vitriol, for instance, or *sulphuric acid*, is a highly acrid and corrosive liquid, but it is composed of tasteless and comparatively inert elements, namely, oxygen, sulphur, and water. The elements, oxygen and nitrogen, which, in a state of *mechanical mixture*, constitute the air we breathe, give rise, when *chemically combined*, to one of the most active agents of the laboratory; namely, *nitric acid*. Again, if sulphuric or nitric acids be combined with caustic potassa, comparatively mild and inert *neutral salts* result, namely, the *sulphate* and the *nitrate of potassa*, in which none of the properties of the component acid and alkali can be recognised. In art, these remarkable changes are made subservient to the most important purposes. A variety of extremely useful compounds are obtained by the union of elements comparatively useless and unimportant; and, by the decomposition of apparently insignificant compounds, their more useful and important elements or components are separated. In nature, analogous changes are more strikingly presented to our observation, and the flower, the shrub, and the tree, are seen gradually to be formed and developed out of materials contributed by the air and soil, and in all respects most dissimilar to the new products of the vegetable: it is true that in these, and in analogous cases which might be taken from the animal kingdom, the mysterious power of vitality interposes; but such changes are nevertheless *chemical*, and legitimate objects of chemical inquiry.

There are many beautiful experiments illustrative of the total change of all obvious properties of substances as a consequence of chemical combination; as one striking instance, we may adduce the mutual action of *oxygen and nitrous gases*; these bodies are respectively permanently elastic fluids, without colour, taste, or smell: when mixed over water, they immediately enter into chemical combination, lose their elastic form, become of a deep orange colour, intensely sour, and of a peculiar odour; in their separate state they are insoluble in water, but the body which has resulted from their combination is perfectly soluble in that fluid.

Change of colour is a common, but also an important, result of chemical action. By exposure to light, air, and moisture, the greater number of colours are gradually destroyed, in consequence of the chemical agencies that ensue; a similar destruction of colour takes place more immediately upon the application of chlorine; and hence these agents are resorted to, to effect the purpose of *bleaching*. In the arts of *dyeing* and *calico-printing*, not only are fugitive colours rendered permanent, but their tints are variously modified, by chemical means. Of the vegetable blues, there are many which are rendered *red* by an acid, and *green* by an alkali; and hence paper stained with the juice of violets, or of the blue flag, or of the petals of the blue heart's-ease, is useful as a *test* of the presence of alkaline bodies. The same principle is applied to other purposes: if, for instance, an acid be gradually added to an alkaline solution, it is found that there are certain proportions in which they exactly *neutralize* each other; that is, a point at which the liquid neither exhibits acid nor alkaline characters. This point may be precisely learned by the above tests, for the solution then has no effect on the vegetable blue; but if either acid or alkali be predominant, that is, if the point of neutraliza-

tion has not been exactly attained, then the test, by the tint which it assumes, announces the predominant element: *green*, if alkaline, and *red*, if acid*.

In other cases, change of *colour* announces the presence of peculiar elements or compounds: thus ferrocyanide of potassium shows iron by a *blue* colour, copper by a *brown*, nickel by a very *pale green*, &c., and there are numberless other tests applicable upon the same principle.

Among the results of chemical action, we may next notice those which relate to the *change of state or form, sustained by the acting bodies*. When substances are burned in the air, they generally pass, as already observed, from the *solid* to the *aëriform* state; and the deflagration of gunpowder is a good instance of such sudden conversion; the converse change, that of *gases* into *solids*, is not so common, yet such cases are not unfrequent. When, for instance, ammonia and hydrochloric acid, both *gases*, are mixed, they immediately condense into a white salt, which is *hydrochlorate of ammonia*. When one part of fuming nitric acid is added to two of strong alcohol, the *liquids* presently disappear, with violent ebullition, in the form of an inflammable *vapour*; and when chlorine and carburetted hydrogen *gases* are mixed, they form a *liquid* of the appearance of oil.

Liquids by combination produce *solids*, and *solids* produce *liquids*. A strong solution of chloride of calcium, mixed with one of carbonate of potassa, soon concrete when shaken together. Excess of a strong solution of tartaric acid, added to strong liquid ammonia, solidify into *bitartrate of ammonia*, with the evolution of *heat*. A mixture of pure alcohol added to a saturated solution of sulphate of magnesia, congeals into a crystallized solid. Crystals of sulphate of soda, rubbed with an equal quantity of nitrate of ammonia, gradually form a liquid. So also the solid amalgams of lead and bismuth, when triturated together, assume a liquid form, and become *cold*.

§ 2.—THEORY OF COMBINATION AND DECOMPOSITION.

CHEMICAL affinity is frequently spoken of under the term *elective attraction*, and is said to be either *simple* or *complex*. It is sufficiently obvious that different bodies are possessed of different attractive powers: and, accordingly, if several be brought together, those which have the strongest mutual attractions will enter first into union: hence has arisen the above term. If I pour dilute nitric acid upon a mixture of lime and magnesia, the acid will dissolve the lime in preference to the magnesia.

* The *test-papers* used in the laboratory are generally *blue litmus* paper, for the detection of acids, and the same *reddened by a weak acid*, for the detection of alkalis; the acids render the former *red*, and the alkalis restore the *blue* of the latter. Paper tinged yellow by *turmeric* is also useful in the detection of alkalis, which change it to a more or less deep *reddish-brown*. Mr. Alfred Taylor re-

commends unsized paper, tinged by a strong infusion of the petals of the red rose, as a more delicate test for alkalis than turmeric: in a very strong alkali it is turned greenish-brown, but when the alkaline solution is very dilute, its reaction is extremely delicate, and it becomes bright green: it will thus indicate alkali where turmeric is not visibly discoloured.

The knowledge of this fact leads to the inference that lime would separate magnesia from its combination with nitric acid; and, accordingly, if lime-water be added to a solution of nitrate of magnesia, nitrate of lime is formed, and magnesia is thrown down or *precipitated*.

Upon this principle *tables of attraction* have been constructed, in which the substance, whose affinities are to be represented, is placed at the head of a column, and the bodies with which it combines beneath it, in the order of their respective attractions; thus the affinity of *sulphuric acid* for several bases would be shown as annexed.

SULPHURIC ACID.

Baryta.
Strontia.
Potassa.
Soda.
Lime.
Magnesia.
Ammonia.

From this table it would appear that *baryta* separates sulphuric acid from its compounds with all the inferior substances, and that *ammonia* is separated by all that are above it; there are, however, many circumstances which interfere with the usefulness and accuracy of such tables; in some cases the volatility, and in others the insolubility of one or other products influence the results; and sometimes there are apparent anomalies in the mutual agencies of bodies, which subvert the order of arrangement. This is especially the case in the decomposition of certain insoluble compounds by soluble salts. One of these, originally noticed by M. Dulong, (*Ann. de Chim.*, LXXXII., NICHOLSON'S *Journ.*, 35 and 36,) has been pointed out by Mr. R. Phillips (*Journal of Science and the Arts*, vol. i., p. 80). He found that, on boiling carbonate of baryta in a solution of sulphate of potassa, sulphate of baryta and carbonate of potassa were formed; and he also found that, on reversing the experiment, by boiling sulphate of baryta in a solution of carbonate of potassa, carbonate of baryta and sulphate of potassa were produced. The inferences deducible from Dulong's researches upon this subject are, that all the insoluble salts are decomposed by the carbonates of potassa or soda; but that a mutual exchange of principles of these salts cannot in any case be complete: and that all the soluble salts, of which the acid forms with the base of the insoluble carbonate an insoluble salt, are decomposed by these carbonates until the decomposition has reached a certain limit, which it does not pass. (URE'S *Dict.*, Art. ATTRACTION.)

In the mutual decompositions of steam by iron, and of oxide of iron by hydrogen, we have another apparent anomalous case of chemical action. When steam is passed over red-hot iron, a portion of it is decomposed, hydrogen gas is evolved, and oxide of iron is formed; whence we should infer that the affinity of oxygen is greater for iron than for hydrogen. But if hydrogen gas be passed over red-hot oxide of iron, steam is formed and the iron reduced to the metallic state; here the affinity of oxygen appears greater for hydrogen than for iron. But in regard to this result it has been ingeniously remarked by Professor Graham (*Elem. of Chem.*, Part 2), "that it is obviously connected with the relative proportion between the hydrogen and the steam which are at once in contact with the metal and its oxide at a red heat. When steam is in excess, water is decomposed, but when hydrogen is in excess, oxide of iron is decomposed; and why? because the excess of steam in the first case is an atmosphere into which hydrogen can diffuse, and the disengagement of that gas is therefore procured; but in the second case the

atmosphere is principally hydrogen, and represses the evolution of more hydrogen but facilitates that of steam. The affinity of iron and hydrogen for oxygen, at the temperature of the experiments, is so nearly balanced that the one affinity prevails over the other, according as there is a proper atmosphere into which the gaseous product of its action may diffuse. This affords an intelligible instance of the influence of mass or quantity of material, in promoting a chemical change; the steam, or the hydrogen, as it preponderates, exerting a specific influence in the capacity of a gaseous atmosphere." The subject of the diffusion of gases referred to in this quotation will be explained in the chapter on *Hydrogen*.

In cases of *simple attraction*, or affinity, one body separates another from its combination with a third. Thus, when potassa is added to a solution of sulphate of zinc (composed of sulphuric acid and oxide of zinc), the oxide of zinc is separated, and sulphate of potassa is produced; or when sulphuric acid is dropped into a solution of nitrate of baryta, sulphate of baryta is precipitated.

In cases of *double decomposition*, two new compounds are produced; as when a solution of nitrate of baryta is mixed with a solution of sulphate of soda, the results are a precipitate of sulphate of baryta, and a solution of nitrate of soda.

These cases of double decomposition are sometimes conveniently illustrated by *diagrams*, which may either be constructed so as merely to show the result of the change, or, where required, they may also exhibit the composition of the acting bodies. In the case just alluded to, the substances before mixture are shown by parallel lines, and after mixture by diagonal lines.

Or a more complete view of the change is given in the annexed diagram, where the bodies, before mixture, are placed upon the outside of the perpendicular lines: their component parts are shown within them; and the new results on the outside of the horizontal lines.

§ 3.—CHEMICAL EQUIVALENTS AND THE ATOMIC THEORY.

A most important result of chemical attraction is, *that bodies combine in certain proportions only*. Thus, in the case just cited, of the combination of baryta with sulphuric acid, to form *sulphate of baryta*, it is found, that in that compound, whether formed by nature or art, by single or double decomposition, the sulphuric acid and baryta always bear a certain definite relation to each other, and are contained in it in the relative proportions, by weight, of 40 sulphuric acid and 77 baryta: that is, these relative weights exactly saturate or neutralize each other; if we suppose sulphate of baryta to be composed of *one atom* of sulphuric acid

and one atom of baryta, then the above numbers may be called the *atomic weights* of those substances, and an atom of sulphuric acid being = 40 and of baryta = 77, the atom of sulphate of baryta will be $(40 + 77) = 117$: these numerical proportions have been sometimes called *representative, or combining numbers*, or more commonly, for a reason which will presently be apparent, *equivalent numbers* or *proportionals*.

But, sulphuric acid and baryta are not elementary substances, they are both compounds, and are consequently termed the *proximate elements* of sulphate of baryta; sulphuric acid consists of sulphur and oxygen, and baryta consists of barium and oxygen; the *ultimate elements*, therefore, of sulphate of baryta, are sulphur, barium, and oxygen: hence also sulphuric acid and baryta are called *compound atoms*; but, in them, the same general law of definite proportionals holds good, for sulphuric acid consists of 16 sulphur and 24 oxygen, which, added together, produce the *compound equivalent* 40; and baryta consists of 69 barium and 8 oxygen, making 77, the *equivalent* of baryta or oxide of barium.

Another essential fact in reference to chemical combination is, that where one substance, A, combines in more than one proportion with another substance, B, the second, third, &c., proportions of B bear a very simple ratio to each other. Thus, mercury combines with oxygen in two proportions, forming the *black oxide* and the *red oxide* of mercury. In the former, 200 parts of mercury are combined with 8 of oxygen, and in the latter, 200 parts of mercury are combined with 16 of oxygen. Here it is obvious that the quantity of oxygen in the *first*, is to that in the *second* compound as 1 to 2. So that, assuming 200 to be the atomic weight of mercury, and 8 the atomic weight of oxygen, we should call the *black oxide* a compound of 1 atom of mercury and 1 atom of oxygen, and the *red oxide* a compound of 1 atom of mercury and 2 atoms of oxygen.

In other cases, the relative proportions of the components are to each other, as 1 to $1\frac{1}{2}$, 1 to $2\frac{1}{2}$, &c.; or, what amounts to the same thing, as 2 to 3, 2 to 5, &c. Thus, there are two oxides of iron; in the *black oxide*, 28 parts of iron are combined with 8 of oxygen, and in the *brown oxide*, with 12 of oxygen. Here, the quantity of oxygen in the *first* is to that in the *second* as 1 to 1.5. There are also two acids of arsenic; in the *arsenious acid*, 38 parts of arsenic are combined with 12 of oxygen, and in the *arsenic acid* with 20 of oxygen; numbers which are to each other as 1.5 to 2.5 or as 3 to 5. These cases, however, are by no means of such frequent occurrence as the former.

The simple ratio which the *weights* of the combining elements are thus seen to bear to each other, involves an equally simple law in respect to combining *volumes*, where substances either exist, or may be supposed to exist, in the state of gas or vapour. Thus, water may be considered as a compound of 1 atom of hydrogen and 1 atom of oxygen, the relative weights of which are to each other as 1 to 8; hence the equivalent of the atom of water will be $(1 \text{ hydrogen} + 8 \text{ oxygen}) = 9$. But oxygen and hydrogen exist in the gaseous state, and the weights of equal *volumes* of those gases (or in other words, their relative densities, or specific gravities), are to each other as 1 to 16; hence 1 *volume* of hydrogen is combined with $\frac{1}{2}$ 1 *volume* of oxygen, to form 1 *volume* of the vapour of water or steam: for the specific gravity of steam, compared with hydrogen, is as 9 to 1.

Hydrogen. 1	Oxygen. 8	=	Steam. 9
----------------	--------------	---	-------------

The annexed diagrams, therefore, will represent the combining *weights* and *volumes* of the elements of water, and of its vapour.

To give another instance: hydrochloric acid gas is considered as a compound of 1 atom of hydrogen and 1 atom of chlorine, their respective *weights* being 1 and 36, and that of the resulting hydrochloric acid 37. Now, the specific gravity of hydrogen to chlorine is also as 1 to 36, and of hydrogen to hydrochloric acid as 1 to 18.5. Hence it is obvious, as in this

Hydrogen. 1	Chlorine. 36	=	Hydrochloric Acid. 37
----------------	-----------------	---	--------------------------

diagram, that 1 *volume* of hydrogen and 1 *volume* of chlorine combine to form 2 *volumes* of hydrochloric acid.

These instances, therefore, will suffice to show that there is the same simple relation in the *volumes* of the compounds as in their *weights*; 1 volume of hydrogen and 0.5 a volume of oxygen producing 1 volume of aqueous vapour; and 1 volume of hydrogen and 1 volume of chlorine producing 2 volumes of hydrochloric acid. In the latter case, and there are many similar instances, the equivalent, or atomic *weights*, correspond with the specific gravities in reference to hydrogen as = 1, the gases combining volume for volume, and producing a compound gas, the volume of which is equal to the united volumes of its constituents.

As a further illustration of the whole subject of definite proportionals, and of the atomic theory, in reference to weights and volumes, I subjoin a table of the compounds of *nitrogen* and *oxygen*: those elementary bodies unite with each other in no less than 5 proportions, and in the simplest ratios, forming two oxides and three acids.

	Atoms or equivalents of Nitrogen and Oxygen.		Weights of the atoms or equivalents of Nitrogen and Oxygen.		Atomic weight of the compound.	Volumes of Nitrogen and Oxygen.		Resulting volume of the compound.
	N.	O.	N.	O.		N.	O.	
1 atom of the protoxide of nitrogen consists of . . }	1	1	14	8	22	1	0.5	1
1 atom of the deutoxide . . }	1	2	14	16	30	1	1	2
1 atom of the hyponitrous acid }	1	3	14	24	38	1	1.5	
1 atom of the nitrous acid . . }	1	4	14	32	46	1	2	1
1 atom of the nitric acid . . }	1	5	14	40	54	1	2.5	

86 Nitrate of Soda.			
Nitric Acid 54	+	Soda 32	
131 Nitrate of Baryta.		72 Sulphate of Soda.	
Baryta 77	+	Sulphuric Acid 40	
Sulphate of Baryta. 117			

It has been above stated that 40 parts of sulphuric acid (or 1 atom) are neutralized by 77 (or 1 atom) of *baryta*. Now we find that 40 parts of sulphuric acid are neutralized by 32 of *soda*; hence, 32 will be the atomic weight, or equivalent of *soda*: if we now refer to nitric acid we shall find that 77 parts of *baryta* neutralize 54 of nitric acid, and that 32 of

soda neutralize the same quantity of that acid. Supposing, therefore, we decompose *nitrate of baryta* by *sulphate of soda*, it follows that the newly-formed salts will still be *neutral*, as in the preceding diagram, to which the *equivalent* numbers of the acting substances are annexed; from which it appears that 131 parts of *nitrate of baryta*, consisting of 77 baryta and 54 nitric acid, are required to decompose 72 parts of *sulphate of soda*, composed of 32 soda and 40 sulphuric acid; and that the results of this decomposition are 86 parts of *nitrate of soda*, composed of 54 nitric acid and 32 soda, and 117 *sulphate of baryta*, composed of 40 sulphuric acid and 77 baryta.

If we, therefore, are acquainted with the *equivalent numbers* of the respective *bases* and *acids*, we at once know the relative quantities required for *saturation*, and consequently the composition of all the *neutral salts*, as will be evident from inspecting the following table:—

ACID.	EQUIVALENT.	BASE.	EQUIVALENT.
Iodic	165	Baryta	77
Bromic	118	Strontia	52
Chloric	76	Potassa	48
Selenic	64	Soda	32
Nitric	54	Lime	28
Sulphuric	40	Magnesia	20
Oxalic	36	Lithia	18
Carbonic	22	Ammonia	17

Here we find, for instance, that 40 parts of sulphuric acid saturate 48 of potassa to form 88 of *sulphate of potassa*, for the decomposition of which would be required 131 of *nitrate of baryta*, containing 54 of nitric acid and 77 of baryta. We may also remark the different quantities of the different bases that are required to saturate a given weight of any of the acids, and *vice versâ*: thus, 77 of baryta, and only 17 of ammonia are required to saturate 54 of nitric acid; and 28 of lime, which are saturated by 22 of carbonic acid, require 165 of iodic acid for the same purpose.

These tables are of great value to those who conduct chemical operations upon the large scale, in the processes of arts and manufactures, guiding them in the quantity of materials which they require, and pointing out the proportions of the products which should be obtained; and when applied, as suggested by Dr. Wollaston in his account of "A Synoptic Scale of Chemical Equivalents," (*Phil. Trans.*, 1814,) to a *sliding-rule*, divided upon the principle of *Gunter's scale*, they furnish the practical as well as the theoretical chemist with an admirable instrument of reference, for the purpose of facilitating and verifying his experimental and calculated results. The form of this instrument, which I recommend to the student*, is a box-wood scale, about two feet two inches long, consisting of a moveable slider with a logometric line of numbers upon it, and a corresponding series of numbers upon the rule itself; upon the *rule* the simple substances are also arranged, each opposite to its respective equivalent: the equivalents of the compounds may, by those who have competent experience, be easily deduced from those of the elements; but, for the convenience of others, and to avoid perplexing the scale with a multiplicity of terms, a separate table accompanies it, containing a

* They are made by Newman, No. 122, Regent Street, and Palmer, 60, Newgate Street.

copious list of compound equivalents. One of the commonest uses of this scale is to ascertain the relative proportions of the elements, in variable quantities of their compounds; for instance, I know that the equivalent of *chlorine* is 36, and of *sodium* 24, and consequently that the equivalent of *chloride of sodium* (or common salt) is $(36 + 24) = 60$. But I wish to ascertain how much of each of the elements is contained in 95 of salt; I therefore bring the number 95 upon the slider opposite to 60 upon the scale, and I now find the number 57 opposite to 36, and the number 38 opposite to 24; hence 95 parts of *chloride of sodium* consist of 57 of *chlorine*, and 38 *sodium*. These and the other uses of this scale are soon learned by a little practice, or by reference to Dr. Wollaston's paper, above quoted, or to Mr. FARADAY'S *Manipulation*.

The doctrine of equivalents furnishes the analytical chemist, in the first place, with a valuable test of the accuracy of his experimental results, which of course, if correct, will not deviate from the above laws; it also enables him, in many instances, to infer the composition of a substance, where direct experiment is unattainable, and this in more ways than one. It was long, for instance, before *magnesium* (the metallic base of magnesia) was obtained, but analogy led chemists to conclude that magnesia was a *protoxide* of a metal, that is, a compound of 1 atom of metallic base, with 1 atom of oxygen. The composition of magnesia, therefore, was inferred from the composition of its *sulphate*, consisting of 1 atom of sulphuric acid = 40 united to 20 of magnesia; now 20, which thus presents itself as the atomic weight of magnesia, must include an atom of oxygen = 8; and 8 deducted from 20, leaves 12 as the inferred weight of the atom of *magnesium*. In the same way the composition of lime was inferred to be 20 calcium and 8 oxygen, for it was found that sulphate of lime consisted of 40 sulphuric acid and 28 lime, and as the oxygen in the *base* of a neutral *sulphate* is to that in the *acid* as 1 to 3, it became obvious that *lime*, or *protoxide of calcium*, must be constituted as above stated.

To give another instance of a similar application of the atomic theory: it was found that chlorine expelled oxygen from lime, and it was ascertained that for every 28 parts of lime so decomposed, 8 parts of oxygen were evolved, and 56 parts of chloride of calcium formed; now deducting 36 (the equivalent of chlorine) from 56, 20 remains, as the equivalent of calcium.

More complicated instances of such extensions of this theory will be given afterwards, especially among its applications to *organic products*; my object in the preceding paragraphs has been to divest it of all hypothetical difficulty, and to present it to the student as involving a series of important practical applications, and as founded upon the basis of experiment. Those who would view it in reference to ancient atomic doctrines, and to the more obscure parts of molecular philosophy, may consult Dr. DAUBENY'S *Essay on the Atomic Theory*, and Dr. PROUT'S *Bridgewater Treatise*.

I shall now merely add a few words in further explanation of the *mode of determining atomic weights, or equivalent numbers*. They are founded upon careful analyses of the simplest combinations of the most important elements: among these we may, as an instance, select *water*; the most

rigid analytical researches concur in representing this fluid as constituted, *per cent.*, of 11.1 hydrogen, and 88.9 oxygen. Now, if we determine upon hydrogen as *unity*, or = 1, then $11.1 : 88.9 :: 1 : 8.009$; or, the hydrogen is to the oxygen very nearly in the ratio of 1 to 8; and assuming water to consist of 1 *atom* of hydrogen united to 1 *atom* of oxygen, the atomic weight of the former being = 1, that of the latter would be = 8. In *hydrochloric acid*, which, as already stated, is a compound of hydrogen and chlorine, these elements bear to each other the relation of 1 to 36; hence 36 is assumed as the *atomic weight*, or *prime equivalent* of chlorine. If I now wish to determine the equivalent of a *metal*, I select its *protoxide*, and ascertain what *weight* of the metal is combined in such oxide, with 8 parts of oxygen: thus in regard to *soda*, I find it constituted *per cent.* of 25 oxygen and 75 sodium; and $25 : 75 :: 8 : 24$; hence the number 24 is assumed as the *equivalent of sodium*. In the same way I may resort to the analysis of *chloride of sodium*, 100 parts of which consist of 60 chlorine and 40 sodium; and $60 : 40 :: 36 : 24$; thus the former result is verified by the analysis of a second compound.

The advantages of assuming *hydrogen* as = 1 or *unity*, and thence deducing the other equivalents, are such as to have led to its very general adoption in this country; as it is the substance which combines in the smallest relative weight, all other substances may be represented by numbers which are *multiples* of its equivalent, and may, for all ordinary purposes of demonstration and research, be *whole numbers*; but to this subject I shall again recur. Some represent hydrogen by 10, and some by 100; in these cases oxygen is of course 80 or 800, and chlorine 360 or 3600, &c. Others adopt *oxygen* as *unity*, in which case hydrogen becomes one-eighth of that unit, and is represented by 0.125, chlorine by 4.5, sodium by 3, &c.; but this system is extremely inconvenient, in consequence of the perpetual and necessary recurrence of fractions, especially as concerns the retention of equivalents by the memory. The equivalents used by Berzelius have reference to oxygen as 100.*

The practical uses and applications of the atomic theory, and further illustrations of the researches upon which it is founded, will occur in almost every succeeding page of this book. It has been justly observed by Sir John Herschel, that the extreme simplicity which characterizes this theory, is itself no unequivocal indication of its elevated rank in the scale of physical truths. (*Prel. Disc.*, p. 305.)

* The extreme confusion resulting from the adoption of a series of equivalent numbers founded upon the assumption that water is a compound of 2 atoms of hydrogen and 1 atom of oxygen, and the incongruities and contradictions which such a hypothesis involves, must be too evident to all who read the works of the eminent authors who speak in that language.

CHAPTER IV.

ELECTRICITY.

MANY of the phenomena of electricity are so remarkable, and so easily exhibited, as long to have attracted general attention: by the natural philosopher they have been studied with much precision and success; and, more lately the discovery of the relation of the *electrical* to the *chemical* powers of matter, and to *magnetism*, has opened an entirely new field of research.

We are ignorant of the *nature* or *cause* of electrical phenomena, but for the convenience of description and discussion it has been customary to refer them to the presence of a highly attenuated and subtile form of matter, which has been termed the *electric fluid*. The existence, however, of such a fluid, or of any peculiar form of matter as productive of electrical phenomena, is entirely hypothetical, and merely assumed to facilitate our reasoning upon the subject.

Inasmuch as electrified bodies are found to present themselves in *two opposite or distinct states*, it has been presumed that the electric fluid exists in all forms of matter; that, under ordinary circumstances, it is in a *state of equilibrium or quiescence*; and that, when this state is so disturbed as to occasion either its *redundance* or *deficiency*, the bodies then become *electrically excited*: upon this view of the cause of electricity, which originated with Franklin, the opposite states have been termed *positive* and *negative*. Others ascribe the phenomena to the presence of *two electric fluids*, supposed to reside in *glass* and *resin*, and hence distinguished by the terms *vitreous* and *resinous*. This hypothesis, which originated with Du Fay, has, under some modifications, also been very generally adopted; it has been assumed that the two electric fluids are universally diffused; that they are infinitely subtile and elastic, and each *repulsive of its own particles, but attractive of those of the opposite kind*; these forces being equal at equal distances, and varying inversely with the square of the distance*. In the ordinary or quiescent state, these fluids are supposed to be *combined* with, and exactly to *neutralize*, each other; and electric excitation is attributed to their *separation*, or to the *decomposition* of the neutral fluid. The first of these hypotheses is recommended by its simplicity, and by the facility with which it enables us to reason upon the greater number of electrical phenomena; but there are cases in which the second appears most consistent; so long, however, as the definitions which we shall afterwards give, of the terms *positive* and *negative*, are distinctly understood, the adoption of either hypothesis is matter of little importance, always bearing in mind that both states, or fluids, are common to all matter, and that they are always coexistent.

* Coulomb supposed the two electric fluids to be possessed of equivalent properties, neutralizing each other's elasticity, like oxygen and hydrogen combined.

§ 1.—ELECTRICAL EXCITATION.—ATTRACTION AND REPULSION.

THE simplest indication of electricity is that which is observed when certain resinous and vitreous bodies are subjected, in a dry and warm state, to gentle friction; as when a piece of sealing-wax is rubbed with flannel, or a glass rod with a piece of silk; in these cases the sealing-wax and the glass acquire the property of attracting and repelling light substances; and they are said to be *electrically excited*. Such properties seem first to have been observed in, and supposed peculiar to, *amber*; and hence the term *electricity*, from the Greek word *ηλεκτρον*, signifying *amber*. Independent of these attractive and repulsive powers, there are other equally curious properties observed in the electrically-excited bodies; in the dark they appear *luminous*, shining, whilst rubbed, with flashes of a blueish light; and, if held near the face, they produce a singular tickling sensation. We find, moreover, that this electrical excitation is transient; that it gradually disappears, and that if the hand be passed two or three times over the surface of the sealing-wax, or of the glass, all signs of electricity are lost. A very light downy feather, perfectly clean and dry, and suspended in any convenient way by a long thread of *white* sewing silk, so as to be as independent as possible of surrounding bodies, is a most delicate and useful indicator of this form of electrical excitation, and may be used in the following experiments.

1. Provide a glass tube, about three feet long, and three-fourths of an inch diameter, and having wiped it perfectly clean and dry, rub it gently with a warm silk handkerchief; it will become electrically excited; and, on approaching the feather, will immediately *attract* it; but, on gently withdrawing, and again bringing it near to the feather, the feather will be steadily *repelled*; so that it will be impossible, for a short time, to get it to touch the tube: after a while, however, it again flies to, or is attracted by, the tube, and then again repelled as before. The annexed cuts (figs. 105, 106,) represent the appearance of the feather when attracted and when repelled.

This apparently trifling experiment teaches us the following important elementary fact: it shows that the feather, having received electricity from the glass by direct contact, is repelled by it; and, consequently, that *bodies similarly electrified repel each other*; for we assume the feather to have *received* a portion of the electricity of the glass, and we know that the repulsion is *mutual*.

2. Rub a large stick of red sealing-wax with a thick roll of dry and warm flannel; the sealing-wax will thus be rendered electrical, and will act upon the feather *apparently* in the same way as the glass; that is, first attracting and then repelling it; and the moment that the feather has received the electricity of the wax, those bodies also become mutually repulsive.

3. Warm a sheet of foolscap paper, folded in the usual way, before the fire, and rub it gently upon a clean polished table with a large piece of Indian rubber; then suddenly open the sheet, and hold its interior towards the feather, which will be attracted and repelled, as in the preceding cases of glass and wax.

There are a number of other substances which become electrical by friction, such as white and black silk drawn gently over each other, as is commonly observed with silk stockings; the back of a clean cat gently rubbed with the dry and warm hand; long, clean, and dry hair, combed in frosty weather; silk tassels and fringes, and so on: but the instances above cited are sufficient, and we may now proceed to a second set of experiments with the same apparatus.

1. Excite the glass tube as before, and electrize the feather, so as to render it *repulsive* of the tube; then bring the excited sealing-wax near the feather, and it will not be repelled as by the glass, but will be immediately *attracted*, by it.

2. Reverse the experiment, and having electrized the feather by sealing-wax, bring the excited glass rod near it, when, instead of being further *repelled* it will be *attracted*.

3. If the feather be suspended between the excited wax and the excited glass, it will vibrate to and fro, being *alternately attracted and repelled*.

These experiments show that there is a *difference in the electricities of the glass and sealing-wax*, and that bodies rendered *repulsive* by glass are *attracted* by wax; and *vice versâ*. We had previously found that bodies similarly electrified repel each other; we now observe that *bodies dissimilarly electrified attract each other*.

These dissimilar electricities, in reference especially to the above methods of producing them, were originally termed *vitreous* and *resinous*; for these, the terms *positive* and *negative* are now more commonly substituted; and the two states may be represented by the symbols *plus*, + and *minus* -. The feather electrized by *glass* is said to be in a *positive* state, and that by *sealing-wax*, *negative*.

Still retaining the simple apparatus that we set out with, we may now proceed as follows:—1. Fold the silk in such a way as to keep the hand as far as possible from the glass tube; then rub the tube with it, and electrize the feather, which will now be *repelled*; whilst it retains this repulsive state, in regard to the tube, approach it with the part of the silk which had rubbed the glass, and it will be found to be *attracted*. From this experiment we should conclude that the *silk* and the *glass* were in *opposite* electric states: we have already called the glass *positive*; the silk, therefore, must be *negative*. The experiment may be varied as follows:—

2. Hold the handkerchief as before, and having warmed it, rub it

with the tube; then bring it near the feather, which it will first attract and then repel: whilst the feather is thus *repelled* by the silk, approach it with the excited glass, by which it will be immediately *attracted*. It is obvious, therefore, that the glass and the silk are in *opposite* states.

3. If we roll up the flannel so as to keep the rubbed part at a distance from the hand, then rub it with the sealing-wax, and bring it to the feather, the latter will be immediately attracted by the flannel, and then repelled: if we now approach it with the excited wax, instead of being more powerfully *repelled*, it will be instantly *attracted*. Hence, having agreed to call the electricity of the wax *negative*, that of the flannel must of course be *positive*; for it is evidently of the opposite or dissimilar kind.

Here, then, we have developed another important electrical law, showing that *one kind of electricity cannot be produced without the other*; that when a body is *positive*, some part of the exciting arrangement is *negative*. In the above case of glass and silk, the former is positive, and the latter negative: and in the case of sealing-wax rubbed by flannel, the wax is negative, and the rubber acquires a positive state.

4. That this is so, may be further shown as follows:—render the feather positive by the contact of the excited glass; then approach it with the excited flannel, and it will be found to be repulsive of the flannel; that is, to possess a *similar* electrical state.

5. Electrize the feather with the excited wax, which will render it *negative*, and then approach it with the excited silk; the silk will continue to repel the feather, and hence is similarly electrized, or *negative*.

Delicate instruments show us, that in almost all cases of *friction*, under the precautions above described, bodies become electrically excited: and that the same body may become either positive or negative, according to the circumstances under which it is excited. Smooth glass, for instance, becomes positive when rubbed with a piece of woollen cloth, but rough glass rubbed in the same way becomes negative; and sealing-wax, which becomes negative when rubbed by flannel, becomes positive when rubbed against tin-foil or mercury. A cat's back is said always to exhibit positive electricity; but it is probable that no peculiar kind of electricity is inherent in any one body; it will even vary with the mechanical state of the surface and the mode of friction; so, polished glass becomes positive when rubbed upon silk, but rough glass becomes negative; both become negative against a cat's back; and when similar substances are rubbed together, that, the friction of which is limited to the least extent of surface, is usually negative: thus, when two similar silk ribands are excited by drawing the one lengthways over the other, that which has suffered friction on its own length becomes positive, and the other negative. The following table, chiefly from the experiments of Cavallo, further illustrates these effects.—(SINGER'S *Elements of Electricity*, p. 33.)

	Becomes	by friction with
The back of a cat . . .	Positive . . .	Every substance tried.
Smooth glass . . .	Positive . . .	Everything except cat-skin.
Rough glass . . .	Positive . . .	Dry oiled silk, sulphur, metals.
	Negative . . .	Wools, quills, wood, paper, sealing-wax, white-wax, common silk; the hand.
Tourmaline . . .	Positive . . .	Amber; air from bellows.
	Negative . . .	Diamonds; the hand.

	<i>Becomes</i>	<i>by friction with</i>
Hare's-skin . . .	Positive . . .	Metals, silk, leather, hand, paper, baked wood.
	Negative . . .	Other finer furs.
White silk . . .	Positive . . .	Black silk, metals, black cloth.
	Negative . . .	Paper, hand, hair, weasel's skin.
Black silk . . .	Positive . . .	Sealing-wax.
	Negative . . .	Hare, weasel, and ferret fur; brass, silver, iron, hand, white silk.
Sealing-wax . . .	Positive . . .	Some metals.
	Negative . . .	Hare, weasel, and ferret fur, hand, leather, woollen cloth, paper, some metals.
Baked wood . . .	Positive . . .	Silk.
	Negative . . .	Flannel.

In regard to the above table, Mr. Singer observes that iron, lead, and bismuth, render sealing-wax negative, the other metals positive; but the least difference in the condition of the materials occasions varieties in the result: with the same rubber (an iron chain) positive electricity may be excited in one stick of wax, and negative in another, if the former be scratched and the latter smooth. *Æpinus* also found that two pieces of plate-glass, when rubbed on each other, were electrical when separated; but that although one was always positive and the other negative, the same plate sometimes exhibited the one, and sometimes the other electricity.

In the following list, the substances become positive with those which follow, but negative with those which precede each other; viz., oxalate of lime, fur, smooth glass, woollen cloth, feathers, paper, silk, gum-lac, rough glass.

§ 2.—ELECTRICAL CONDUCTORS AND NON-CONDUCTORS.

THERE are some substances which, when examined by the above-described methods, are not observed to become electrical. If we, for instance, rub a cylinder of *metal* with flannel or silk, it is perfectly inert when brought near the feather: but the exception here is apparent only; the substances previously used, such as glass and sealing-wax, are *non-conductors* of electricity; that is, they receive and retain it upon the excited surface only; but a bar of metal is a *conductor*, and when electricity is produced upon it by friction, it immediately spreads over its whole surface, and is carried off, as it were, by the hand, to the earth and all surrounding conductors. To show that the metal actually is excited in the same way as glass, attach it to some non-conductor: for instance, attach a cylinder or plate of brass to a stick of sealing-wax, which may serve as its handle; then rub the brass against a dry and warm flannel, and, taking care not to touch any part of it with the hand, bring it near the feather, which will be attracted, and then repelled, precisely as by the glass and wax. In these cases the metals usually acquire negative electricity.

We now, then, can understand the division of bodies into *conductors* and *non-conductors*. There are also a set of bodies intermediate between the above extremes, which are called *imperfect conductors*. The non-

conductors, readily exhibiting their electricity by friction, are often called *electrics*, in opposition to the metals and other good conductors, which are called *non-electrics*. The electrics, from their power of preventing the passage or transfer and escape of electricity, are also sometimes termed *insulators*. Thus, a brass rod mounted upon a stem or foot of glass, or sealing-wax, or a wire suspended by silk thread, is said to be an *insulated conductor*.

The metals are by far the most perfect conductors; next to them come well-burned charcoal and plumbago; then some of the concentrated acids, and strong saline solutions. Water, rarefied air, most vapours, and many stony bodies and metallic ores, are imperfect conductors. Shell-lac is the most perfect non-conductor, and an excellent substance to use wherever good insulation is required*. Sulphur and wax are also non-conductors; and so is glass, which, though in this respect much inferior to some other substances, is from the convenience of its application, the usual insulator employed in all common electrical apparatus. Raw and bleached silk stands high upon the list of non-conducting substances; but dyed silk is often a partial conductor, in consequence of the substances used to colour it: hence, in the above experiments, we have advised *white* silk for the suspension and insulation of the feather. It is also stated by Henley, that black hair conducts better than white (*Phil. Trans.* 1776), as illustrated in the case of a bullock struck by lightning. Dry air, and baked wood, are non-conductors. There is a gradual transition in bodies from what are termed perfect conductors, to perfect non-conductors; the following list exhibits the principal of these:—

CONDUCTORS.	IMPERFECT CONDUCTORS.	NON-CONDUCTORS.
Metals	Water	Spermaceti
Charcoal	Damp wood	Glass
Plumbago	Alcohol	Sulphur
Fused chlorides	Damp air	Fixed oils
—— iodides	Some oils	Resins
—— salts	Vegetable and	Ice
Strong acids	animal bodies	Diamond
—— alkaline solutions.	generally.	Shell-lac
		Oxalate of lime
		Dry gases and air.

There is no constant relation between the *states* of bodies and their conducting powers. Among *solids*, for instance, metals are conductors; resins non-conductors: among *liquids*, strong alkaline and acid solutions are good conductors; water is an imperfect conductor; many oils are non-conductors. Potassa, protoxide of lead, chloride of sodium, iodide of zinc, many salts, and other bodies, are non-conductors in their solid state, but conduct when liquified by heat. Sulphur, phosphorus, resins, iodide of sulphur, and several other solid bodies, do not, on the contrary, acquire conducting power on assuming the liquid state. (FARADAY, § 394,

* According to Erman, (*Gilb. Ann.*, xi., 143), a thread of gum-lac insulates ten times as well as silk. A needle of sealing-wax remains for some days excited. A capillary bore lessens the insulating power of glass. The dissipation

of electricity by the atmosphere is nearly in the triplicate ratio of its moisture. It is also stated, that an electric jar is discharged if put into a vibratory state, as by sounding it like a harmonica.

&c.) Glass, when cold, is a non-conductor; but when red-hot, it is a conductor: the diamond is a non-conductor: but pure and well-burned charcoal, which is merely another form of diamond, is among the best non-metallic conductors*.

We may form some idea of the retardation which electricity suffers in passing through imperfect conductors, from the statement of Mr. Cavendish (*Phil. Trans.*, 1776), according to whom, iron-wire conducts 400 million times better than pure water; sea-water, (with one-thirtieth of salt) 100 times better; and a saturated solution of salt, 700 times better.

The enormous rapidity of the progress, or supposed progress of the electric fluid through long trains of conductors, was first experimented upon by Watson (*Phil. Trans.*, 1748): he could observe no perceptible time occupied in its passage through a circuit of 12,276 feet. This curious subject has lately been investigated by Mr. Wheatstone (*Phil. Trans.*, 1834, p. 583), according to whom, electricity moves through a copper wire, with the velocity of 400 feet in the ten-thousandth part of a second; or, through 4 million feet in a second. To this subject we shall afterwards recur in referring to the conducting powers of the metals, in regard to voltaic electricity.

§ 3.—ELECTROSCOPES AND ELECTROMETERS.

Electroscopes and *electrometers* are instruments by which changes in the electrical states of bodies are rendered evident, and their intensities measured.

One of the simplest of these (fig. 107) consists of two small pith-balls, suspended by very fine thread or silver-wire to the end of a small insulated conductor. When this receives electricity, the balls diverge, and the nature of the electricity by which they are diverged may be judged of, by approaching the conductor with a piece of excited

sealing-wax: if the divergence *increases*, it is the same as that of the wax or *negative*; if it *diminishes*, it is opposite to that of the wax, or *positive*.

Where a more delicate test of the presence of electricity is required,

we substitute for the pith-balls two small slips of gold-leaf; and as these are apt to be deranged by the slightest motion of the air, it is necessary to enclose them in a glass cylinder, sufficiently capacious to allow of their divergence. They are connected with the brass cap of the instrument, which is used in the same way as the preceding. This is commonly called *Bennet's gold-leaf electrometer*.

The delicacy of the gold-leaf electrometer is much increased by an improvement in the insulation of the leaves, which we owe to the late Mr. Singer.

It will appear hereafter that all substances may conduct electricity, and that the terms conduction and non-conduction therefore are so far incorrect: in employing them as above we refer

to their common acceptance. See, in reference to this subject, FARADAY'S *Experimental Researches*, § 1320 and 1326.

The instrument is constructed, as usual, with a glass cylinder surmounted by a brass cap, but the insulation is made to depend upon a glass tube, about four inches long, and one-fourth of an inch internal diameter, covered both on the inside and outside with sealing-wax, and having a brass wire of a sixteenth or twelfth of an inch thick, and five inches long, passing through its axis, so as to be perfectly free from contact with any part of the tube, in the middle of which it is fixed by a plug of silk, which keeps it concentric with the internal diameter of the tube. *a* is a brass cap screwed upon the upper part of this wire; it serves to limit the atmosphere from free contact with the outside of the tube, and also defends its inside from dust; to the lower part of the wire the gold-leaves are attached, and the whole mounted as usual, as represented, in section, by fig. 109. When a gold-leaf electrometer is to be employed in atmospherical investigations, the contrivance described by Mr. Ronalds (*Quart. Journ.* ii. 249) may be conveniently applied to it.

The *kind of electricity* by which the gold leaves are diverged may be judged of, as before, by approaching the cap of the instrument with a stick of excited sealing-wax: if it be *negative*, the divergence will increase; if *positive*, the leaves will collapse; upon the principle of the mutual annihilation of the opposite electricities; or that bodies similarly electrified repel each other, but that when dissimilarly electrified they become mutually attractive.

To ascertain the actual repulsive and attractive powers appertaining to weakly-electrified bodies, Coulomb ingeniously availed himself of the principle of torsion, and thus constructed his *electrical balance*. It consists of a fine metallic wire, *a*, fig. 110, one end of which is attached to the screw *b*, and to the other is suspended the horizontal needle *c*, composed of gum-lac or other non-conductor, and armed at one extremity with a gilt pith-ball, counterpoised at the other end by an index. The conductor *d* is a small wire with a ball at each end, passing through the glass receiver in which the needle is suspended, and having its lower ball opposed to that of the needle. By the screw *b*, the two balls are brought into contact, and the index then points to *o*, on the divided scale of degrees. On communicating a very feeble electrical power to the conductor, it transfers it to the moveable pith-ball, and *repels* it a certain number of degrees, proportional to the intensity of the acquired electricity, and measured by the power of torsion which it exerts upon the fine wire. By experiments made with this electrometer, it would appear that the electrical powers follow the law of gravitation, in being *in the inverse ratio of the squares of the distances of the acting bodies*. In the most delicate construction of the instrument, a single silk-worm's thread or a filament of spun glass is used instead of the wire.

By means of the gold-leaf electrometer, constructed as above, we dis-

cover the existence of very slight states of electrical excitation, which elude all common methods of detection. If the cap of the instrument be gently struck with a silk handkerchief, a powerful divergence may be given to the leaves, resulting from the friction of the metal and silk; if blown upon by a pair of bellows, electrical excitation is also indicated, depending probably upon the friction of the air upon the metal; and it will be found in the sequel, that we conveniently avail ourselves of this instrument to detect the evolution of electricity in a variety of other cases.

To determine the kind of electricity by which the leaves are repelled, we approach them, as before directed, either with an excited stick of sealing-wax, or a glass rod; if the divergence is increased by the former, it is *negative*; if diminished, *positive*; if increased by the glass, it is *positive*; if diminished, *negative*. In consequence of the law of excita-

tion by induction, it is sometimes supposed that this method of merely *approximating* the instrument, instead of actually touching it by the excited wax or glass, might lead to erroneous conclusions; but if we examine a little more particularly into the state of things, we shall find that, consistently with that law, *electro polarity* will be produced, and that consequently, the *gold leaves* will acquire the *same* electricity as that of the wax or glass, although the surface of the brass plate or cap of the instrument, immediately opposed to the wax or glass, may be in an opposite state.

Thus, let N (fig. 111) represent a piece of excited wax, *negative*; P the cap of the electrometer, *positive*; N the gold leaves, *negative*, that is, *similarly* electrified to the wax.

§ 4.—INDUCED ELECTRICITY.

WE have laid it down as a general rule, that no electrical *attractions* exist, except between bodies in *opposite* or *dissimilar* electrical states; and have shown that when any electrified body, such, for instance, as an excited stick of sealing-wax, is brought near other non-electrified bodies, they have a tendency to mutual attraction. This tendency exists among all surrounding substances; but such, of course, only, as have freedom of motion, are observed to move towards the excited electric: such as the suspended feather, particles of dust, and any other light and moveable bodies. Now, as these are *attracted* by the electrified body, it follows that they must previously be thrown into an *opposite* electric state, by the mere *proximity* of the excited electric; and this is really the case: whenever an electrified body is brought near to another in an un-electrified state, the surface of the latter, opposed to the former, becomes *oppositely* electrical, and is consequently *attracted* by it.

Electricity is thus said to be *induced* in the surrounding bodies by the vicinity of any excited electric: thus, when a highly-electric cloud hovers over the earth, that portion of the earth's surface opposed to the

cloud, becomes in an oppositely electrical state, and consequently attractive of the cloud; thus, during a thunder-storm, we often see an electric cloud perch upon the summit of a hill, and remain there till it has discharged its electricity, when it is wafted quietly away.

Electricity by induction presents many curious phenomena, which may here be stated generally, and more particularly explained afterwards. We have already said, that when an electrified body approaches another which is in its ordinary state, the surface of the latter opposed to the electrified body acquires an opposite state: this opposite electrical state, however, only belongs to the opposed surface; for the other side of the body, though also electric, is *dissimilarly* so. This statement may be rendered more intelligible by the following diagram:—Let *a*, fig. 112, represent a brass needle freely moving upon its centre, which is supported upon a glass foot. *b*, a conductor, *positively* electrified, and within a few inches of the pith-ball *c* attached to one of the points of the needle. We shall now observe that *c* is *attracted* by *b*, and may therefore infer that it is *negative*; and that this is really the case may be shown by

bringing near to the ball *c*, a stick of excited sealing-wax, by which it will be *repelled*. But if we now bring the sealing-wax towards the ball *d*, it will be *attracted* by it: here, then, by the *proximity* of the conductor *b*, we have induced in the needle *a* an *electro-polar* state; *b* being positive, *c* is negative, *d* positive. To explain this further by the help of our hypothesis: let us suppose the natural or quiescent electricity of *a* to be disturbed by the presence of *b*, which causes a portion of it to be repelled or driven from *c* to *d*. The end *c*, therefore, is *negative*, or *minus*, that is, it has *less* than its natural portion of electricity; and *d* is *positive*, or *plus*, because in it electricity is *accumulated*: in the centre *a* there will be a neutral point, in which no electricity is manifest. The state of the needle therefore is such, that negative electricity is accumulated at *c* and positive at *d*, and that they each gradually decrease towards the centre *a*. On the removal of the disturbing body *b*, the needle reverts to its ordinary state; or, in other words, the electrical equilibrium is restored.

The *polar arrangement* thus caused by induced electricity, may be carried to any extent: thus, suppose *a* in the preceding diagram, fig. 113,

to represent a body *negatively* electrified, *b* would become positive, *c* negative, *d* positive, *e* negative, and so on, through any extent of conductors, the last being in communication with the earth. Thus the feather attached to the insulated conductor at *b*, is attracted towards *a*, and the feather *c* attracted by *d*; these feathers and surfaces being respectively in *oppositely electrical states*.

These illustrations will suffice to explain the meaning of the term *induction*, or induced electricity, without a knowledge of which many of the electric phenomena we are about to advert to, would be unintelligible: we shall afterwards find that it presents some very extraordinary consequences in reference to the distribution and accumulation of electricity, and the disturbance of the electrical equilibrium.

The actual electro-polar state of a conductor under induction is well shown as follows: place two gold-leaf electrometers about 18 inches apart, and connect their caps by an insulated wire lying across them; then approach *one* of them with an excited glass tube, which will cause both to diverge; whilst they are in this diverged state, lift off the intermediate wire, and then remove the inducing tube, and each electrometer will retain its divergence: on examining that which was nearest to the excited glass tube it will be found *negative*, and that which was at the other extremity of the wire will be *positive*; if we now, by means of a wire, with an insulated handle, reconnect the two caps, both electrometers will collapse, and lose all signs of electricity, showing that the negative and positive states were co-equal: a piece of wire with a handle of gum-lac is a convenient connector for the electrometers.

When in these experiments, the conductor electrified by induction is insulated (as it must be to exhibit its polar state), the accumulation of either electricity is of course feeble, being limited to the decomposition of the quantity of neutral electricity contained in it; but if one end of the conductor be connected with the ground, the supply is comparatively unlimited: this may be well shown by presenting the knuckle or a brass ball held in the hand to the prime conductor of the electrical machine; the opposed surface becomes oppositely electrical by induction, and a succession of sparks pass; but if the person be insulated, the induction is limited, as in the insulated conductor, and only two or three sparks are observed to pass.

The following experiments on induction I have taken from Mr.

Faraday's *Lectures*, and they are excellently adapted to class illustration. Provide two hollow brass hemispheres, or wooden ones covered with tin-foil, each mounted upon a lacquered glass stem standing upon a wooden foot (fig. 114), so that when placed together they may form the insulated sphere (fig. 115). Having thus placed them, approach them with an excited glass rod, and then remove it. On examining them by a gold-leaf electrometer, they will be found perfectly unelectrified; Repeat the approach of the

excited glass rod, and whilst it is retained in its situation, separate the hemispheres by the removal of one of them by means of the wooden foot, taking care that they remain insulated, and immediately withdraw the excited rod. It will then be found (by help of the electrometer) that each hemisphere is in an oppositely electrical state as represented by the letters N and P.

If whilst the insulated sphere (fig. 115) is rendered temporarily electrical by induction, it be touched for a moment by the finger, it will be found on first removing the finger, and immediately afterwards the inducing excited tube, that the globe now retains a negative charge, and will even give a spark, the positive electricity having been carried away by the hand, and not able, therefore, to return so as to reproduce the neutral state.

The subject of induction has been acutely studied, and successfully developed by Faraday (*Researches*, Series xi.) Before his researches the phenomena were presumed to depend upon an action taking place in straight lines through non-conducting media, the particles of the medium not being themselves affected: whereas it would appear from his experimental investigation of this extensive and intricate subject, that "induction is in all cases an action of contiguous particles, consisting in a species of polarity, instead of being an action of either particles or masses at sensible distances;" that it may be propagated not only in straight but in curved lines. Mr. Faraday's views have been so clearly abridged and illustrated by Mr. Daniell, that I shall, with his permission, avail myself of the following quotation and diagrams from his *Introduction*, in further illustration of this subject.

"We have seen," he says, "that one electric force cannot be produced without an exactly equal development of the other; and upon more attentive examination we shall find that no kind of matter, either conducting or non-conducting, is capable of receiving a charge in any way of one kind of electricity independently of the other, or without calling forth an equal amount of the opposite force in adjacent bodies. It was formerly supposed that the electric fluid was confined to the surfaces of bodies by the mechanical pressure of the non-conducting air, in the midst of which all our experiments are carried on; but the fact is, that the electric force originating or appearing at a certain place is propagated to, and sustained at, a distance, through the intervention of the contiguous particles of the air, each of which becomes polarized as in the case of insulated conducting masses, and appears in the inductive body as a force of the same kind exactly equal in amount, but opposite in its direction and tendencies.

"Such a forced arrangement of the molecules cannot be made to appear to the eye in the case of the air, but is established by the most perfect inductive reasoning; and a similar disposition may actually be exhibited by substituting a liquid non-conductor for the air under similar circumstances. If we take a tall, wide-mouthed glass vessel, and place it upon the prime-conductor of the electrical machine, taking care that there may be a good metallic communication through its bottom, and then fill it with spirit of turpentine containing some threads of white silk about one-eighth of an inch in length disseminated through it, they will be little

affected upon turning the machine till a metallic conductor is held near the surface of the liquid. Upon presenting, however, such a body, they will immediately erect themselves, and, collecting from all parts, will attach themselves to each other end to end, and form a continuous chain from the conductor to the exterior metal, towards which they will always incline as it is moved in different directions. These particles will adhere together with considerable force, as may be felt by touching them with a rod of glass; but the moment the conductor is discharged, they fall upon their sides, and sink to the bottom. If, instead of silk threads, we occasion particles of gold-leaf to float in the spirit of turpentine, the resemblance will be perfect; for, on approaching them with a rod of metal, when the conductor is charged, they immediately start on end as if endued with life, assume the polar state, attract each other end to end, but owing to their perfect conduction, discharge their electricity by minute sparks.

“Now the solid threads of silk accurately represent the fluid particles of the spirit in which they float, or of the air which is interposed between a charged conductor and surrounding bodies, and obviously assume a polar state, exactly resembling that of insulated conductors in similar circumstances.

“In the annexed diagram (fig. 116), let A represent an insulated electrified

ball placed within an uninsulated metallic sphere, $a b c d$, filled with a non-conducting medium, whose particles are represented by the small included circles. These will be all thrown into a polar state, indicated by the shading, resembling the silk particles in the spirit of turpentine: their dissimilar poles will be all turned towards the ball A , and in this way their combined influence will be thrown upon the metallic sphere, $a b c d$, which will thus have a force of the opposite kind to that upon A , developed upon it, of exactly equal amount, but diffused over the larger surface. It is conceived that the polarized particles are capable of affecting each other, not only in straight lines as in the quadrant $A b c$, but in lines diverging from their centres, as shown in the quadrant $A b a$.

"Each polarized particle is in active relation, not only to a line of particles in some definite direction from it, but to all those which are contiguous to it. Hence, there is a lateral diffusion of force, and the lines of inductive action, when unobstructed, tend to spread as from a centre; or may assume a curved direction when any obstacle opposes their free radiation.

"In consequence of the lateral action of the particles upon one another, if $B c$ (fig. 117) be an obstacle interposed in the course of the induction from A to $a b c d$, the particles 1 2 3 4 5 6 7 will be protected from the influence, but the induction will affect the particle 8, by the bending of the lines of force on each side of it.

"The particles 1 2 3 4 5 6 7 themselves, although here represented in their natural state, will be affected by a reflex action; but will be polarized to a much lower degree than those within the influence of the direct action."

§ 5.—ELECTRICAL MACHINES.

IN the preceding details we have availed ourselves of the simplest apparatus, in order to explain the leading and principal laws of electrical excitation; all the experiments are easily made, and their results include some of the most important facts connected with the subject, to which, in the sequel, it will be necessary frequently to recur. For the further practical prosecution of these experiments, an *electrical machine* is indispensable; this, therefore, we may now proceed to describe.

The best electrical machine for experimental purposes, and for the general use of the student, is represented in the following wood-cut. It is commonly called *Nairne's machine*. (See fig. 118.) It consists of a *glass cylinder* A, about 10 or 12 inches in diameter, and 15 to 20 inches in length, turning between two upright pillars of glass, B B, fixed to a stout mahogany base. Two smooth *metal conductors*, equal in length to the cylinder, and about one-third of its diameter, C C, are placed parallel to it upon two glass pillars D D, which are cemented into two sliding pieces of wood E, by which their distance from the cylinder may be adjusted. One of the conductors has a *cushion*, F, attached to it (by a bent metallic spring) nearly as long as the cylinder, and about one inch or an inch and a half wide, to the upper part of which is sewed a *flap* of

silk, *G*, which should reach from the cushion over the upper surface of the glass cylinder, to within about an inch of a row of points attached to the side of the opposite conductor. The conductor to which the cushion is attached is called the *negative* conductor; the other collects the electricity of the glass, and is called the *positive* conductor: *H* is an adjusting screw to regulate the pressure of the cushion upon the cylinder. The motion of the cylinder is in the direction of the silk flap, and may be most simply communicated by a handle attached at *I*, or, if necessary, by the multiplying wheel *K*. It is obvious, that in this form of the electrical machine, the cylinder and the cushion correspond to the glass tube and silk rubber employed in the former experiments, and that all the phenomena appertaining to the excited *tube* will be exhibited by the cylinder *A*, and the conductor opposed to it, whilst those of the excited *silk* or rubber, will belong to the cushion *F*, and to its conductor.

To put this electrical machine into good action, every part should be made *perfectly clean and dry*. The cushion is then anointed with *amalgam*, and applied by a gentle pressure to the cylinder. If *positive* electricity is required, it may be received from the conductor bearing the points, that supporting the cushion being, at the same time, uninsulated by an attached wire, passing from it to the stand; if, on the contrary, *negative* electricity is required, it may be obtained from the insulated cushion and its conductor, the other conductor being uninsulated.

The best *amalgam* is composed of one part of tin and two of zinc melted together, and mixed, while fluid, with six parts of hot mercury in an iron mortar. This mixture is triturated till it becomes a fine powder, which is then formed into a tenacious paste with hogs' lard.

Another form of the electrical machine, usually called the *plate machine*, consists of a circular glass plate *A* (fig. 118), mounted upon an axis, and rubbed by two pairs of cushions, as shown at *BB*. The brass conductor *C* has its points opposed to the plate, and is insulated by the glass stem *D*: *EE* are double pieces of oil-silk passing from the cushions to near the points. The whole is supported by a stout mahogany frame, and motion is given to the plate by the winch *F*.

These electrical machines have considerable power; they are easily cleaned and excited, and are more portable than the cylinders; but as they cannot be conveniently insulated, the negative electrical power cannot be so well exhibited; for the general purposes therefore of experimental illustration, the former machines are preferable.

When either of these electrical machines have been for some time out of use, they require to be thoroughly cleaned: for this purpose, the conductors and cushions must be removed, and the cylinder or plate cleansed with a little whiting and spirit of wine; it must then be wiped perfectly dry with a clean, warm, and soft cloth. It is a common custom to set the machines before the fire, but this is apt to soften their cemented joints, and endangers the plate or cylinder; the former especially is often cracked by incautious warming, and, in this case, the crack generally commences at the axis, and gradually proceeds towards the circumference; its progress may often be successfully checked by drilling a hole through the plate at the point of the crack. *Dryness* rather than warmth of the air is requisite for the activity of the electrical machine; it should, therefore, be kept in a dry room. When the glass parts of the machine are perfectly clean and dry, the cushions, freshly amalgamated, may be applied; their pressure upon the cylinder or plate should be very moderate, and they also should be dry and warm. The brass parts of the machine and of other electric apparatus are very commonly lacquered, which ought not to be, as it often interferes with their uses: the brass knobs especially should be clean and polished, but not varnished*.

§ 6.—GENERAL PHENOMENA OF ELECTRICITY OF TENSION.

WHEN the electrical machine is in good order, and the atmosphere dry, it produces a *crackling noise* when the plate or cylinder is turned, and flashes and *sparks of light* are seen upon various parts of the glass, passing from the cushion to the conductor: if the knuckle be held near the conductor, sparks pass to it through some inches of air, with a peculiar noise, and excite a slightly-painful sensation in the part upon which they are received. These, and the other phenomena we may now notice, are especially characteristic of electricity of *tension*.

It is conjectured that the cause of the *spark* thus perceived is the sudden compression of the air or medium through which the electricity passes, and it is always probably attended by a proportionate *elevation of temperature*, as is shown by the power of the spark to inflame spirit of wine, and some other easily inflammable compounds.

In these electrical machines the surface of the glass becomes positive by friction upon the rubber or cushion, which becomes negative; and as the cylinder or plate is kept in progressive motion, it follows that, provided there be a means of carrying off its positive electricity, it will continually receive a new supply from the uninsulated rubber; if, on the contrary, no means of conducting it away be resorted to, it will perpetually annihilate itself by retransmission to the cushion. But when the cushion is insulated, the abduction of electricity must be very limited: hence, to the full and perfect operation of the electrical machine, two circumstances must co-operate; there must be a means of withdrawing the generated electricity from the surface of the glass, and of preserving the supply to the cushion: of these, the former is effected by the opposed prime conductor; the latter, by connecting the cushion by a metallic chain or wire

* There are several splendid electrical machines of large dimensions and great power, at the Royal Institution; among them, one of two plates of four feet diameter each, revolving upon the same axis.

with the earth. We accordingly observe, in examining the operation of the electrical machine,—1st. That the electricity in either conductor is extremely feeble when they are both well insulated. 2ndly. That when one conductor is uninsulated, the power of the other is proportionately augmented; in the positive conductor, because then the other draws uninterrupted supplies from the earth; and in the negative conductor, because the positive freely transmits, and hence is left in a state rapidly to receive. 3rdly. That the cushion and the surface of the glass are always in opposite states. 4thly. That the negative and positive electricities excited, bear precisely that relation which enables them, when combined, to neutralize each other: in other words, that the *deficiency* of electricity on the one side is exactly such as to be restored by the *redundancy* on the other.

Those who advocate the hypothesis of two distinct electric fluids explain the action of the electrical machine as follows: they suppose that by friction the neutral electric fluid of the rubber is decomposed, the positive adhering to the glass, and the negative to the surface of the cushion; that the positive surface of the glass in its turn decomposes the neutral electricity of the prime conductor, the negative element of which is attracted by the positive of the glass so as to reproduce upon it the neutral state, whilst the prime conductor having thus lost negative electricity is left more or less highly positive, not by receiving electricity from the revolving glass, but by having parted with its own negative fluid to the glass.

The appearance of the *electric light* is modified by the density of the medium through which it passes. In common air, short sparks are straight, or nearly so, and long ones zigzag; the former are brilliant, especially at their extremities; the latter usually of a paler or redder hue. In condensed air, the electric spark is bright and white; in rarified air, it is of a reddish tinge, and faint and divided; in the more perfect vacuum of a good air-pump it is of a purplish hue, and only visible in a dark room. In a good Torricellian vacuum the light is faint blue; and in the most perfect vacua which can be obtained, it is scarcely visible, and of a greenish tint. In gases, the electric spark usually appears most brilliant in those which are most dense; in hydrogen gas, it is faint and red; in carbonic acid, it is vivid and white. It is also modified by the nature of the surfaces from and to which it passes.

By the aid of Nairne's electrical machine, all the phenomena of excitation, and of attraction and repulsion, may be very conveniently studied. The conductor attached to the cushion is *negative*, and that opposed to the cylinder *positive*; the former, therefore, represents the *sealing-wax*, and the latter the *glass*, employed in the experiments above described. If we attach two pith-balls to either conductor, they *repel* each other; but if one be attached to the negative, and the other to the positive conductor, they *attract* each other. If the two conductors be connected by a metallic wire or chain, all electrical appearances cease, showing that the negative and positive powers are exactly such as to *neutralize* or *annihilate* each other: and in this case, a current of electricity traverses the wire, passing from the positive to the negative conductor; and, when a break is made in it, a succession of sparks pass between the divided extremities. This

wire, during the passage of the electricity through it, exhibits other and most important properties, which we shall afterwards have to advert to.

Whenever a spark passes, it announces the annihilation of the opposite electrical states, they having been previously brought into existence by induction. The knuckle held near the positive conductor becomes negative; and when the opposite states have acquired a certain degree of intensity, a spark passes, and the state of excitation is at an end.

There is an important circumstance attending the distribution of quiescent electricity, which is, that it belongs to surfaces only, and is so far independent of quantity or mass of matter, that a hollow sphere receives the same charge as a solid one. Coulomb found that an excited globe of metal afforded no indication of electricity in its interior; and that an excited hollow cylinder, open at the ends, imparted no charge to a small insulated disc, introduced into, and brought into contact with, its interior. The following illustration of the same fact is due to Biot. He suspended a metallic sphere by a silk thread, and exactly covered it by two moveable thin metallic hemispheres, which, by insulating handles, could be applied and removed at pleasure. On communicating a charge to this sphere *with* its exterior coating, he found, upon its removal, that the whole of the charge was carried away upon it, and that the sphere remained without electricity: and again, on charging the sphere, and then applying the coating, the whole of the electricity manifests itself upon the latter, and may again be carried away as before. This experiment requires some dexterity in its performance, but is perfectly satisfactory in its results. In the same way, if any metallic vessel, such as a pail or pot, be insulated and charged with electricity, on bringing an insulated carrier-ball to its exterior, electricity may there be carried away and communicated to a gold-leaf electrometer; but on applying the carrier-ball, carefully to its interior, it will not receive a trace of electricity. The cause of this apparent paradox will be evident by a reference to Mr. Daniell's diagrams. Thus, if we suppose $abcd$, (fig. 116,) to be a hollow sphere charged with electricity, an insulated ball, a , introduced into and touching any part of its interior could receive no charge, "because, being surrounded by a surface in one electrical condition, it could not induce the opposite state by polarising the surrounding air, by which alone a charge could be sustained: this will be at once obvious by supposing the ball, a , shaded the same as the circle, $abcd$, to denote a similar state of electricity, when the polarised state of the particles represented in the diagram will be seen to be impossible."

It has been concluded that in a solid body, having the form of a sphere, the electric fluid is accumulated in a very thin stratum at its surface, and everywhere equally, so that a spark, taken from any part of the surface, is of equal length, and the electricity has not more tendency to escape from any one part than from any other; its *intensity*, therefore, is said to be everywhere equal. But if we alter the form of the surface, we at the same time alter this equal distribution of electricity. If two similar spheres be placed in contact, there will be two points of greatest and equal intensity on their opposite sides in a line with their point of contact, and at that point the electricity will be null. In an ellipsoid, also, the greatest accumulation appears at the *extremities* of the longer axis,

and there the *intensity* of the electricity is at its maximum, and increases with the length of the axis: so that if the ellipsoid be considerably elongated, the intensity is very feeble at the equator, and very great at the poles; and in cylindrical bodies, the greater the proportion of the length to the breadth, the greater will be the intensity at the extremities. Coulomb found that in a cylinder, 30 inches long, and 2 inches in diameter, the intensity of the electricity at the ends was to the intensity at the middle as 2·3 to 1. If the conductor be elongated into a point, the intensity there becomes so great as to draw to itself nearly the whole of the electricity; hence, wherever points project beyond the general surface, there is a tendency in the electricity to pass off. The tendency, therefore, of the electric fluid to pass off from surfaces, or in other words its pressure against the air, in the language of the mathematical electricians, is considered proportional to the square of its quantity: so that, if the electric accumulation at four different parts of a conductor be as 1, 2, 3, and 4, the pressure against the air at those parts will be as 1, 4, 9, and 16. These important influences of the forms of the surface have been well put by Mr. Daniell. "If two balls of unequal diameters be placed together, the maximum intensity of the extreme point of the smaller sphere will be higher than that of the corresponding point of the larger, and by adding a series of balls in contact with each other, all gradually decreasing in size, the intensity will increase upon the smaller as the diameter decreases. We can conceive a succession of such balls gradually diminishing till the series ends in a mere point, at which the electric tension will be at its maximum. In consequence of this law of distribution, a powerful dispersion of electricity takes place from all bodies of a pointed form, the intensity upon them increasing to such an extent that the surrounding insulating medium of air gives way before it, and no longer suffices to restrain it."

§ 7.—ILLUSTRATIONS OF ELECTRICAL ATTRACTION, REPULSION, AND INDUCTION, AND OF THE INFLUENCE OF POINTS.

THE statement of facts respecting electrical attraction, repulsion, and induced electricity, admits of many elegant and amusing illustrations by the electrical machine; the apparatus for which, with instructions for its use, will be found in the repositories of the philosophical instrument makers.

The *head of hair*, which stands on end when electrized, serves to illustrate the direction of the lines of induction, each hair, as if repelled by its neighbour, radiating towards the nearest point in an oppositely induced state, and consequently converging towards the finger when held near them. A similar experiment may be made by placing a person upon an insulated stool, in connexion with the conductor of the electrifying machine; his hair will diverge as in the above figure.

The following is a sketch of the simplest form of the *electrical peal*

of bells, which ring by the attractions and repulsions of small clappers suspended between them. The bells are arranged as follows: *a* is a brass hook and wire by which they are suspended to the conductor; *b* the bells attached to the wire by a brass chain, the centre one being suspended by silk; *c* the clappers also suspended by silk. The electricity received at *a* is slowly dissipated by the edges of the bells, the ringing of which is occasioned by the alternate attractions and repulsions of the insulated clappers. A better arrangement consists in suspending the central bell by silk in the same way as the clappers, and connecting it with the table by the wire *c*.

Dancing figures, cut out of light paper, may be made to exhibit very ridiculous movements by a little management in turning the machine. For this purpose, suspend a brass plate from the conductor of the machine, and beneath it, at the distance of four or five inches, place a similar brass plate connected with the ground; on this put the paper figures; when the upper plate is electrified, they rise and perform a dance by their motion between the plates.

A good experiment, illustrating attraction and repulsion, consists in attaching a wire, with a blunt point, to the prime conductor, and holding over it a clean dry bell-glass, the interior of which will thus receive a superficial charge; if it be then set upon the table over a dozen pith-balls of different sizes, they will dance up and down in it for several minutes, until they have nearly carried off its redundant electricity.

Among the experiments particularly illustrative of electrical induction, we may notice the *luminous tubes* and *words*, in which a number of

123

sparks are made to pass between small pieces of tin-foil, so arranged as to produce in a darkened room a variety of figures and devices. In the *luminous tube*, a number of small spangles of tin-foil are pasted spirally round a tube about half an inch in diameter, and within a very short distance of each other; upon holding the brass-ball *A* to the prime conductor of the machine when in good action, the other end of the tube being uninsulated, a beautiful succession of small sparks is seen between each of the little discs of foil. The opposite electrical states are here produced by induction throughout the series of spangles, the passage of the sparks indicating the momentary annihilation of the electricities. Let the following figures, for instance (fig. 124), represent three of the discs or spangles:

it follows, then, that 1, being held near to the positive conductor, will become *polar*, as represented by the letters *N* and *P*: and the

124

whole series, whatever may be their number, will be thrown into the same state as the conductors represented in the figure at page 249, and remain so till the spark passes.

The influence of points in receiving and carrying off electricity has already been adverted to, and may be further elucidated by the following experiments. If we hold a pointed wire to the prime conductor, it rapidly and silently draws off its electricity, and sparks cannot be taken from it by the knuckle, or a brass ball, while the point is in its neighbourhood; or if we attach a pointed wire to the conductor, there is the same convection of electricity; and on holding the hand near the point, we perceive a peculiar coldness, or wind, as it were, which has been called the *electrical aura*: it is even sufficient to blow out a candle held near it. This arises from the secession of the electrified particles of air in consequence of the inductive force concentrated upon the point.

If the point itself be moveable, it will of course be itself reacted upon, and upon this principle a variety of ingenious apparatus has been constructed, such as *fly-wheels*, *orrieres*, and so on. A simple instance is shown in the annexed cut (fig. 126), in which a *fly* with four arms, each terminating in a point at right angles to the arm, is balanced at its centre upon a pointed wire stuck into the prime conductor. The escape of the electricity from the points, and its action upon the adjacent air, causes the fly to revolve rapidly.

If these experiments be made in the dark, it is observed that a point held towards the *negative* conductor has the appearance of giving out a *brush of light* (fig. 127); but when held to the *positive* conductor, a *luminous star* or point is all that is observed (fig. 128). These appearances have been supposed to demonstrate the existence of an *electric fluid*, which, in the one instance, is supposed to be *escaping from*, and, in the other, *received by*, the point: but these affections of light cannot be admitted as proofs of the existence of any distinct form of matter*.

* The philosophy of the electric discharge by sparks, brushes, &c., has been minutely studied and ably illustrated by Mr. Faraday, more especially in the 12th series of his *Researches*; he has also described its appearance in various media or dielectrics; his details upon these subjects are extremely curious and important, but are too extended to be here quoted, and scarcely admit of such abridgment as to bring them within my

limits, I must, therefore, content myself by referring the reader to the original. It will be observed that the brush differs from the spark in being "a discharge between a bad or a non-conductor, and either a conductor or another non-conductor; the spark ensues where an insulating dielectric is interposed between two conducting surfaces in opposite states of electricity; and then if the actions be continually increased in strength, or

§ 8.—OF INDUCTION THROUGH GLASS, AND OF THE LEYDEN JAR.

FROM what has been said respecting *induced electricity*, and the electrical accumulation dependent upon it, it will appear that the intervention of conductors and non-conductors, or imperfect conductors, is requisite to the existence of the phenomena. In the cases cited, the non-conducting medium through which it takes place, or the dielectric, is the *air*; we shall now show that induction may also take place through *glass*.

For this purpose it is only necessary to excite one side of a clean, dry pane of glass, by rubbing it with a piece of silk; and, on holding a feather or pith-ball to the other side of the pane, it also will be found electrical. If we now examine the nature of the electricities by which the glass plate is charged, it will be found that the rubbed side being *positive* the opposite side is *negative*.

In the same way we may charge a plate of glass with the opposite electricities, by holding it to the prime conductor of the machine: in this case sparks will often appear to pass through the glass; but, on removing it, the side which has *touched the conductor* will be found *positive*, and the opposite side *negative*.

As glass is a non-conductor, it is difficult to spread the electricity equally over its surface: this, however, may easily be effected by coating both sides of the pane with thin tin-foil to within about an inch and a half or two inches of the edge, as shown in fig. 129. If we now communicate electricity to one side of the plate, the other, not being insulated, will become oppositely electrical, and in this way a *charge* will be acquired by the plate: if we now, by means of a bent wire, make a communication between the two sides of the coated pane, a

bright spark will pass, and the accumulated electricities will be immediately annihilated.

We avail ourselves of arrangements of this sort for the purpose of accumulating electricity, which may thus be accomplished to a great and powerful extent; but the pane of glass is an inconvenient form of apparatus for the purpose, and we usually substitute for it a phial or jar, as represented in fig. 130, coated inside and out with tin-foil to within three or four inches of its mouth. A brass wire, surmounted by a knob, is then made to communicate with the interior coating, and the apparatus is ready to receive its charge of electricity, precisely upon the same principle as the pane of glass. This is called the *Leyden jar or phial*, the method of arrangement having been accidentally discovered in 1700 by Muschenbrock, of that University. The glass should be thin, and, as far

otherwise favoured, either by exalting the electric state of the conductors, or bringing them nearer each other, or diminishing the density of the dielectric,

a *spark* at last appears, and the two forces are for the time annihilated, for the discharge has occurred."

as possible, uniform throughout; for phials or jars which are very thick, or much thicker in one place than another, are unfit for the purpose.

If we now hold the jar by its outer coating, and present the knob near to the conductor of the machine, a succession of sparks will pass into it, at first very rapidly, afterwards more slowly, and at length ceasing altogether. The jar is then *charged*; and if a communication be now made by a metallic wire, from the outer to the inner coating, a bright spark, attended by a snapping noise, will pass from the knob, after which no further effect will be produced, the jar having been *discharged*. The jar may also be charged by receiving the sparks upon the outer coating, whilst the knob is held in the hand.

The wire used for the above purpose should be mounted with balls at its ends, and is usually called a *discharger*, *a*; it is sometimes *jointed*, for the convenience of applying it to large and small jars, and mounted upon a glass handle, *b* (figs. 131, 132).

If, having charged the jar, and holding its exterior coating in one hand, we touch the knob with the other, the spark passes as before, and we perceive a peculiar and very painful sensation at the wrist and elbows, and across the breast, which is called the *electric shock*. It is painful for the moment only, and leaves little other permanent impression than that resulting from fear or surprise.

In charging the jar as above described, if we keep it in contact with the conductor, and the machine is in good action, we observe, after a time, that flashes of light pass across the uncoated interval, which are soon followed by a loud crack or explosion, and a long and brilliant spark passes from the wire to the coating. In this case the electricity has been accumulated to such a degree of intensity as to discharge itself spontaneously over the exterior uncoated interval.

To ascertain the relative charge which the jar has received, and its power of retaining that charge, we employ the *quadrant electrometer*, (fig. 133,) contrived by Henley. It consists of a round stem of metal, seven or eight inches long, surmounted by a ball, to which is attached a semicircle, most conveniently made of thin ivory: in its centre a pin is fixed, on which a slender slip of cane, about four inches long, with a pith-ball at its other end, turns freely, and traverses the semicircle as an index; the lower half of the semicircle is divided at the edge into ninety degrees. When this instrument is electrified, there is, of course, a tendency to repulsion between the moveable ball and the stem: the ball therefore recedes, and carries the index over the graduated circle, to a greater or less extent, in proportion to the intensity of the electric charge. The repulsion is at its maximum when the index stands at right angles to the stem, or at 90° upon the scale. This electrometer may be fixed upon the prime conductor, or upon the knob of the jar. The latter is often a very convenient place for it,

because, having charged the jar and removed it from the conductor, we see by the behaviour of the electrometer how far the jar retains its charge.

There are many other electrometers which are applicable to these high charges of electricity, among which Cuthbertson's *Balance Electrometer*, and Lane's *Discharging Electrometer*, will be found very useful. Mr. Harris, of Plymouth, has also described a balance electrometer, (*Phil. Trans.*, 1834, p. 213,) by which the mutual attraction of oppositely electrified surfaces may be very accurately estimated and compared; and in experiments in which it is required to charge Leyden jars or batteries with known proportions of electricity, the *unit-jar*, contrived by the same electrician, is also a most useful piece of apparatus.

In charging the Leyden jar many hundred sparks are observed to enter it, which, when it is discharged, are all concentrated into one; hence the brilliancy of its light, the loudness of the explosion, and the acuteness of the sensation which it produces.

When the jar is in direct communication with the conductor of the machine, it diminishes the intensity of its electricity, and consequently admits of a greater change in its electric state before any given resistance is overcome, or force of attraction manifested. This is shown by attaching the quadrant electrometer to the conductor of the machine, which, when turned, immediately causes it to rise to its full extent; but when the interior coating of the jar is in union with the conductor, the machine must be turned for some time before the rise of the electrometer attains its maximum.

The *annihilation* of *positive* by *negative* electricity, and the reverse, may be strikingly shown by attaching the quadrant electrometer to a Leyden jar, and giving it a certain charge—say to twenty degrees—from the *positive* conductor; then transfer it to the *negative* conductor, and whilst apparently receiving a negative charge, the electrometer will gradually fall, and, at length, all electrical accumulation disappear: then, as the jar acquires its negative charge, it will again rise, and may be again discharged by transferring it to the positive conductor.

The power of the Leyden phial, as a source of electrical accumulation, being dependent upon the opposite states of its two surfaces, it is obvious that one of them must always be connected with the ground, in order that it may acquire its charge. If we suspend a jar by its knob (a thin globular jar answers best for this experiment) to the positive conductor of the machine, its outer coating, being surrounded by dry air, cannot give off any of its electricity, and consequently it will receive no charge so long as it remains thus insulated; but if we hold the hand near the outer coating, sparks of positive electricity will pass off, and the jar acquire a charge. This is a good experiment, illustrating the Franklinian theory of electricity, which supposes the electric fluid to be present in all bodies, but to manifest itself only when its equilibrium is disturbed. Thus, when we charge a jar in the usual way, we *add* to the electricity of its interior coating, whilst its exterior *throws off* an equivalent quantity: so that the former becomes *positive*, or *plus*, and the latter *negative*, or *minus*: but if the jar be *insulated*, the electricity cannot escape from the outer coating, and consequently the jar cannot be charged. The theory of two

fluids assumes that the positive electricity deposited upon the inner surface of the jar repels the positive electricity from the outer surface of the jar, and attracts the negative electricity: that, therefore, every spark which passes from the conductor to the knob, occasions an increase of positive electricity upon the inner surface, and of negative electricity upon the outer surface, and that the mutual attraction between these two electricities prevents their spontaneous escape, and occasions a greater accumulation of each upon their respective surfaces: that when a communication by a perfect conductor is made between the two surfaces, the electricities rush into combination, and all appearances of accumulation or excitation are at an end.

The following experiment further illustrates this subject:—Take two Leyden jars of similar size (fig. 134); insulate one of them by fixing it upon a glass stand, *a*, and place the other on the table, with its knob half an inch distant from the coating of the insulated jar, the knob of which should be placed at the same distance from the conductor of the machine. For every spark that passes to the knob of the first jar, *b*, there will be a similar spark pass *from* its coating to the knob of the second jar, *c*, and both jars will become *similarly* and equally charged. As, therefore, the second jar is thus charged by sparks emitted from the exterior surface of the first, and as their charges are equal, it follows that for every portion of electricity *added* to one side of the coated glass, a corresponding or equivalent portion *leaves* the opposite surface.

The preceding wood-cut shows the proper arrangement of the apparatus for this experiment.

Upon this principle *a jar may be charged by the transfer of its own natural electricity from one surface to the other*: for instance, suspend a jar to the *positive* conductor of Nairne's machine, and connect its *outer* coating by a wire with the *negative* conductor or rubber, the whole being in a state of insulation, so as to prevent the access of electricity from the earth. A few turns of the machine will charge the jar; that is, the electricity which is thrown *into* its inner surface by the positive conductor, is abstracted *from* its outer surface.

This experiment is further instructive, as showing the *impermeability of glass to the electric fluid*, for the conductor and the rubber of the machine are separated from conducting contact with each other by the thickness of the glass jar only, and a considerable accumulation of electricity takes place, which the contact of the thinnest film of conducting matter, or the slightest fissure in the glass, would effectually prevent. When the glass of the Leyden jar is very thin, it does occasionally happen that it is perforated by a powerful charge; in this case a small round hole is observed in the glass, and the jar is rendered useless.

It has been said above, that a plate of glass not covered by tin-foil, may be charged by contact with the prime conductor: *the metallic coating, therefore, is not essential to its charge*, but its principal use is, by its conducting power, to spread the electricity over the surface of the glass, and to enable it, when the discharge is made by uniting the opposite surfaces, to be carried off *at once* in a single spark. Jars are sometimes made with moveable coatings; these may be charged as usual, and the coating removed and again replaced, when it will be found that they still retain their electricity, which appears to adhere to the surface of the glass.

Mr. Faraday's researches have disclosed new views respecting the extraordinary condition of the glass, or of the molecules of the glass in a charged jar, and as constituting the polar *dielectric*; each layer of particles being, as he assumes, thrown into a peculiar polar condition, which, if retained, constitutes insulation, but which, if lowered by the communication of power from one particle to another, constitutes conduction: he regards insulation and conduction as only extreme degrees of one common condition or effect, and shows that these two apparently perfectly dissimilar conditions may be associated by numerous intermediate links.—(See Series xii. of his *Researches*.)

The following experiment to a certain extent illustrates the condition of the charged glass in the above experiments; if we apply to particles what we here observe in regard to masses. Apply the uncoated sides of two thin plates of glass, each coated upon one side only, to each other, and charge them; on attempting to separate them they are found to adhere together, and, on separating them, the uncoated side of the plate which had touched the conductors will be found positive, and that of the other negative.

Mr. Faraday's views of the nature of induction led him to infer the existence of a *specific inductive power* peculiar to each substance, and he proved it by very decisive experiments (*Researches*, series xi.), in which, among other forms of apparatus, he employed what he has termed a *differential inductometer*, one of the forms of which consisted of two insulated brass plates placed within a certain distance of each other, one of which was connected with the cap of a gold-leaf electrometer: on electrifying the other, it acted by induction through the air upon the electrometer, and produced a certain extent of divergence of the leaves: plates of different substances were then substituted for the air interposed between the plates, and the divergence was either increased or diminished, according to the relative facilities with which induction took place through the interposed substances: he thus ascertained that the specific inductive capacity of air being assumed as = 100, that of glass is = 176, of shell-lac = 200, and of sulphur = 224. With respect to aëriiform bodies, he ascertained the curious fact that they all possess the same power of sustaining induction; no variations either of their density or elasticity produced any change in the electric tension, till rarification was carried so far as to enable the discharge to take place across them; hot and cold, and dry and damp air were compared, but no difference was observed.

In speaking of the different states of electricity, the terms *quantity* and *intensity* are frequently used to indicate the different phenomena which it exhibits: the former implies the actual quantity of electricity in any body;

and the latter, or the term *tension*, signifies the state of electricity indicated by the electrometer, and its power of flying off from surfaces, and passing through a certain stratum of air or other ill-conducting medium. The meaning of these terms will be more evident when we are considering the electricity of voltaic combinations: in the mean time, as regards the electricity of the machine, they may, perhaps, be further illustrated as follows:—If we suppose a charged Leyden phial to furnish a spark, when discharged, of one inch in length, we should find that another uncharged Leyden phial, the inner and outer coating of which were communicated with those of the former, would, upon the same quantity of electricity being thrown in, reduce the length of the spark to half an inch; here, the *quantity* of electricity remaining the same, its *intensity* is diminished by one-half, by its distribution over the larger surface. Upon the same principle, if a long metallic riband be coiled up and placed upon the cap of a gold-leaf electrometer, the leaves of which are fully diverged by a sufficient charge of electricity, it will be found upon uncoiling the riband by means of an attached silk thread, so as still to preserve insulation, that the leaves collapse to a greater or less extent, in proportion to the quantity of the riband uncoiled, and that, upon allowing it again to coil up, they again diverge; here the extent of the divergence is proportionate to the intensity of the electricity, which, the quantity remaining the same, is increased or diminished inversely as the surface exposed.

It is obvious, that the *extension of surface* will be attended with a greater superficial exposure to the unelectrified air; and hence it might be expected, that a similar diminution of intensity would result from the vicinity of the electrified surface to the ground, or to any other body of sufficient magnitude in its ordinary or unexcited state. That this is the case, may be shown by diverging the leaves of the gold-leaf electrometer, and in that state, approaching the instrument with an uninsulated metallic plate, which, when within half an inch of the electrometer-plate, will cause the leaves to collapse; but on removing the uninsulated plate, they will again diverge, in consequence of the electricity regaining its former intensity. The same fact is shown by the *condensing electrometer*.

The influence of the air upon the retention of electricity by surfaces has already been mentioned, and may be further illustrated by the Leyden phial, which, if charged, and placed under the receiver of the air-pump, gradually loses its charge during exhaustion, and if the experiment be made in the dark, the two electricities are seen annihilating each other by flashes of light. This tendency of electricity to fly off from surfaces, is always greater in rare than in dense media, and consequently the length of the spark, or *striking distance*, (as when a charged jar is discharged,) supposing the *quantity* of electricity to remain constant, will vary, inversely as the density of the air; and, according to Mr. Harris, the resistance to the passage of the charge varies as the square of the density of the air; and Dr. Turner found the striking distance for the same charge greater in hydrogen than in air, and greater in air than in carbonic acid gas. If electricity, though of great intensity and small quantity, be made to pass through a non-conducting medium, its effects are curiously increased; and in this way it may be made to perforate glass; as when we surround

a pointed wire by wax or oil, and take sparks from it through a thin phial. The passage of electricity through air of different densities, and in vessels and tubes of different shapes, lengths, and diameters, gives rise to a number of beautiful and very interesting experiments. The good conducting power of flame, and the facility with which it discharges electricity, may also probably be referred to its rarity. But all these phenomena, and others which have been more exclusively referred to the air's pressure, are principally referable to changes in the inducing power of the dielectric, or surrounding medium, and are beautifully consistent with those views of the nature of specific induction which Mr. Faraday has deduced from his experimental researches (Series xii.). In reference to the pressure of the atmosphere, as influencing the retention of electricity upon the surfaces of conductors, Mr. Faraday well remarks, that "it associates two such dissimilar things as the ponderous air and the subtle and even hypothetical fluid or fluids of electricity by gross mechanical relations; by the bonds of mere static pressure. My theory, on the contrary, sets out at once by connecting the electric forces with the particles of matter; it derives all its proofs, and even its origin, in the first instance, from experiment; and then, without any further assumption, seems to offer at once a full explanation of those and many other singular, peculiar, and, I think, heretofore unconnected effects."

The Leyden jar furnishes a striking illustration of that case of induction before alluded to (p. 258), in which the two electric forces are so limited in their direction as to present no indications external to the apparatus employed; thus if we charge a jar, and then, by an insulated handle or silk thread, remove the charging ball and wire, such jar will present no electric appearances on examining either coat by an insulated carrier-ball; if such a ball having been in contact either with the inner or outer coat be examined by the gold-leaf electrometer, no signs of electricity can be detected: the two forces are confined to the coatings, or to the particles of the dielectric contiguous to them, and are entirely engaged to each other by induction through the glass. But if we now replace the charging-ball and rod, by an attached silk thread, then the part projecting above the jar will give a powerful charge to the carrier-ball, and the outside coating of the jar, if it be insulated, will be found in the opposite state; each strongly inductive to surrounding objects; and after these trials, on discharging the jar, we have evidence, by the usual phenomena, of the annihilation of the previous inductive state.—(FARADAY, Series xiv., § 1682.)

The power of the Leyden jar, in receiving and retaining electricity, is proportioned to its surface, but a very large jar is inconvenient, and difficult to procure; the same end is attained by arranging several jars, so that by a communication existing between all their interior coatings, their exteriors being also united, they may be charged and discharged as one jar. Such a combination is called an electrical *battery*, and is useful for exhibiting the effect of accumulated electricity.

The discharge of the battery is attended by bright light, and by a considerable report, and if it be passed through small animals it kills them; if through fine metallic wires, they are ignited, melted, and burned; and gunpowder, cotton sprinkled with powdered resin,

and a variety of other combustibles, may be inflamed by the same means.

The mechanical force that accompanies the electric discharge is shown by the perforation of paper, the tearing of the leaves of plants, and of pieces of wood, and the breaking of plates of glass, through or over which it is made to pass; chemical decompositions may be effected by it, and it produces magnetic effects consistent with the laws which we shall afterwards point out*.

We observe, therefore, that certain attractive, repulsive, and inductive powers belong to electricity in a quiescent state, and that when in motion, it produces heat, light, chemical effects, and magnetism.

§ 9.—OF THE ELECTROPHORUS, AND CONDENSER.

THE *electrophorus* (fig. 135) is often used as a permanent source of electricity, and may sometimes be conveniently and economically substituted for the electrical machine, especially in the chemical laboratory. It consists of two *metallic* plates, *a a*, with an intervening plate of *resinous* matter, *b*; for the latter equal parts of shell-lac, resin, and Venice turpentine are generally used, the mixture being carefully melted in a pipkin, and poured, whilst liquid, into a wooden or metal hoop, of a proper size, placed upon a polished surface of glass or marble, from which it easily separates when cold; it should be about half an inch thick, and the smooth surface being uppermost, the lower side should be covered with tin-foil, or attached to any other metallic plate; a polished brass plate, with a glass handle *c* attached to it, is then placed upon the upper surface of the resinous plate, and of rather smaller diameter. The resin having been previously excited by gentle friction with a piece of dry fur, the instrument will be found to exhibit the following phenomena.

Upon raising the brass plate by its insulating handle, it will be found very feebly electrical; replace it, touch it with the finger, and again lift it off by its handle, and it will give a spark of *positive* electricity. This process may be very often repeated without fresh excitation, which circumstance, as well as the nature of the electrical charge, shows that the elec-

* The intensity of the heat produced even by the common electric spark, is such as easily to inflame alcohol, kindle gas flames, and so on; the reason why this heat is not, in common cases, observed, is the excessive rapidity of the effect, of which, as appears from Mr. Wheatstone's experiments, the term *instantaneous* gives us but a very imperfect idea; hence it is, that the spark taken from the hand *has not time to burn*, though a succession of sparks limited to the same spot produces inflammation; and we shall afterwards find,

that by diminishing the rapidity of the progress of electricity, or using a continuous current, we get a variety of effects *completed*, of which, the excessive transiency of the common electric spark either from the machine or Leyden jar, prevents the accomplishment. Any continuous current of electricity, which we can obtain by the common machine, is extremely small in *quantity*, hence the difference between its effects and those which we shall afterwards witness in other cases of electric excitation.

tricity of the moveable brass plate is not *directly* derived from the resin, but that it depends upon *induction*: this is more obvious by considering the upper plate, not as in absolute contact with, but merely very near the resinous disc, which, from the minute irregularities upon its surface, is really the case; the negative electricity, therefore, of the excited resinous plate, is communicated from a few points of contact to the brass plate, upon its first application, and then, the latter is precisely in the state of a conductor opposed to, but not touching, an electrified surface; and consequently in due condition to be rendered permanently electrical by induction, when occasionally uninsulated by the contact of the finger.

With this instrument, one phenomenon of induction may be shown, which cannot be so well exhibited by any other; namely, the increased capacity, as it is sometimes called, for electricity, of the conductor under the influence of induction. The brass plate, when placed upon the resin, may be regarded as in a polar state; the lower surface near the resin being *positive*, the upper surface being *negative*. Upon touching the upper surface with the finger, it instantly *acquires* electricity, loses its apparent polarity, and becomes positive, giving, upon removal, a positive spark to any conductor. It is obvious that in this case the brass plate represents one end of a conductor of indefinite extent. That the quantity of electricity received by the plate is equivalent to that given out, is supposed to be shown by the following experiment:—place the metallic upon the resinous plate, and touch the former with the knob of a Leyden phial; then touch the cap of an electrometer with the knob of the phial, and it will give a certain *negative* divergence to the leaves; raise the plate and present the knob of the jar to it, a spark will pass; and, upon applying the jar a second time to the electrometer, the leaves will entirely collapse, showing the exact annihilation of the former negative by the latter *positive* charge.

When the electrophorus is placed upon an insulating stand, its lower plate is always found in an opposite electrical state to the upper one, so that in this respect its plates resemble the coatings of a Leyden jar: it also well illustrates the great inductive capacity of the lac or resinous compound.

When an insulated surface is opposed to another which is not insulated, so as to be affected by it by induction, the electricity communicated to the former suffers an increase of tension on breaking the induction by removing the opposed uninsulated conductor: this property is exhibited as follows:—Provide a brass plate, three or four inches in diameter, and drop upon its lower surface three small spots of sealing-wax; place it upon a similar plate, forming the cap of the gold-leaf electrometer, from which it will be separated about a twentieth of an inch by the three small insulated legs of wax. Connect the upper plate with the ground, by touching it, and give a very feeble electrical charge to the electrometer, so as scarcely perceptibly to diverge its leaves; then suddenly remove the upper plate, by which the induction towards it will be broken, and the tension of the electricity suddenly increased, so as to cause a very considerable divergence of the leaves.

The plates employed in this experiment have been called *condensers*.

They are sometimes placed perpendicularly, as in fig. 136, and the uninsulated plate *a* is supported by a wire and joint, so as to be brought as close as possible to the insulated plate *b*, without touching; the latter is in communication with the electrometer, and having received its charge, the moveable uninsulated plate is drawn back, as in *c*, and the intensity of the electricity displayed.

Sometimes the condenser is directly attached to the electrometer, as shown in fig. 137: *a* the insulated plate; *b* the moveable plate in communication with the ground.

The general phenomena of induction already explained are also illustrated by this form of apparatus; and it will now be evident that what is termed electrical *repulsion* depends upon induction to surrounding bodies, as in the case of the gold leaves of the electrometer, or of two similarly electrified pith-balls, which cannot induce towards each other, but do so in all other directions through the molecules of the surrounding medium or dielectric. In the condenser above described, when the plates are near each other so as only to be separated by a very thin stratum of air, induction chiefly takes place from *a* to *b*; but on removing *b* to a distance, the induction of the gold leaves to the nearer surrounding objects becomes manifest, and they appear to repel each other. In these cases, more or less of the inductive force is diverted from one direction into another.

§ 10.—OF NATURAL ELECTRICAL PHENOMENA.

HAVING considered electricity in relation to its most obvious and ordinary effects, we may proceed briefly to examine its influence as a *natural agent*.

Electricity is called into action, upon a grand and sublime scale, in the production of the *thunder-storm*. It has been by no means satisfactorily ascertained to what the electric accumulation, that in such cases ensues, is to be attributed, but it is probably referable to a variety of causes, and connected with some peculiar power in masses of aerial vapour to receive and retain electrical charges, which do not admit of artificial imitation, and cannot, therefore, be satisfactorily explained by experiments upon a smaller scale.

The ancients referred the thunder-storm to the collision and attrition of clouds and vapours, impelled and agitated by currents in the higher regions of the atmosphere; and, in more modern times, before the discoveries in electricity which have been noticed, subtile inflammable and sulphureous exhalations were supposed to exist in the air, and, by their ignition and explosion, to produce the effects.

At an early period of electrical science, an analogy between the electric spark and lightning was suggested. Mr. Grey and Dr. Wall, and afterwards the Abbé Nollet, (*Leçons de Physique Expérimentale*, t. iv. p. 314, Paris, 1748), hinted more explicitly at this analogy. "If any one," says he, "should take upon him to prove, from a well-connected comparison of phenomena, that thunder is, in the hands of Nature, what electricity is in ours; that the wonders we now exhibit at pleasure are small imitations of those great effects which alarm us, and that the whole depends upon the same kind of mechanism; should it be shown that a cloud, formed by the action of the winds, by heat, and by a mixture of various exhalations, is, when opposite to a terrestrial object, as an electrified body when at a certain distance from one that is not electrified, I confess, such an idea, if well supported, would afford me infinite pleasure, and, that it may be supported by many plausible arguments, is obvious to any one well versed in the history of electrical phenomena. The universality of the electric matter, the rapidity of its action, its heat, and its activity in inflaming other bodies; its property of striking them externally and internally, even to their smallest parts; the remarkable instance we have of this effect in the Leyden experiment; the notion which may be legitimately adopted of the effects that might be supposed to arise from a much greater accumulation of electric power: these, and many other points of analogy which I have for some time meditated upon, almost induce me to believe that, in taking electricity as a foundation, one might form much more perfect and plausible hypotheses respecting the origin of thunder and lightning than any that have been hitherto suggested."

Such are the suggestions of Nollet respecting the analogies between electricity and lightning: their truth was afterwards proved by Franklin, who, like his predecessors, meditating upon the similarity of their effects, traced out further resemblances, and at length hit upon the happy expedient of sending up a common kite to an electric cloud, and thus experimentally demonstrating their identity. The following are the particulars of this curious discovery. (*Encyclop. Brit.* Art. ELECTRICITY.)

Franklin begins his account of the similarity of the electric fluid and lightning, by cautioning his readers not to be staggered at the great difference of effects in point of degree, since from that no fair argument could be drawn of the actual disparity of their nature. It is, he says, no wonder that the effects of the one should so far exceed those of the other; for if two gun-barrels electrified will strike at two inches distance, and make a report, at how great a distance 10,000 acres of electric cloud must strike and give its fire, and how loud must be the crash. He then adds, that flashes of lightning are generally crooked and waving, and so is a long electric spark; that lightning, like common electricity, strikes the highest and most pointed objects in its way, in preference to others, such as hills, trees, towers, spires, masts of ships, points of spears, &c.; that it takes the readiest and best conductor; that it sets fire to inflammable bodies, rends others to pieces, and melts the metals. Lightning, he adds, has often been known to strike people blind, and the same happened to a pigeon which had received a violent shock of electricity; in other cases it has killed animals, and they have also been killed by electricity.

Reasoning on these effects, and having observed that pointed conductors appear to attract electricity, he conceived that pointed rods of iron attached to buildings might draw from clouds their electric matter, without noise or danger, and dissipate it at their termination in the earth: the following is his memorandum upon this subject:—"The electric fluid is attracted by points; we do not know whether this property be in lightning, but since they agree in all particulars in which we can already compare them, it is not improbable that they agree likewise in this. *Let the experiment be made.*"

In the year 1752, while waiting for the erection of a spire in the city of Philadelphia, not imagining that a pointed rod of any moderate height would answer the purpose, it occurred to him, that, by means of a common kite, he might have ready access to the higher regions of the atmosphere. Preparing, therefore, a large silk handkerchief, and two cross sticks to extend it on, he took the opportunity of the first approaching thunder-storm, and went into a field, where there was a shed proper for his purpose. But, fearing the ridicule which might attend an unsuccessful attempt, he communicated his intention to no one but his son, who assisted him in flying the kite. A considerable time elapsed without appearance of success, and a promising cloud passed over the kite with no effect, when, just as he was beginning to despair, he observed some loose threads upon the string of the kite begin to diverge and stand erect; on this, he fastened a key to the string, and on presenting his knuckle to it, was gratified by the first electric spark that had thus been drawn from the clouds; others succeeded; and when the string had become wet by the falling rain, a copious stream of electric fire passed from the conductor to his hand. What were Franklin's emotions upon this occasion, it is easy to conceive: we are told that when he saw the fibres of the string diverge, and the spark pass, "he uttered a deep sigh, and wished that the moment were his last;" he felt that his name would be immortalized by the discovery.

Franklin pursued these experiments with much assiduity and success: he erected an insulated iron rod to conduct the electricity of the clouds into his house, and performed with it nearly all the experiments for which he had before employed the common machine; and that no opportunity might be lost of making such experiments, he attached a chime of bells to the electric rod, which gave him notice, by their ringing, of the electric state of his apparatus.

Two French gentlemen, Messrs. Dalibard and Delor, probably were the first who experimentally verified Franklin's hypothesis. The former prepared his apparatus at Marly, near Paris; the latter at his house, which stood upon high ground in that city. Dalibard's apparatus consisted of an iron rod forty feet long, the lower end of which was brought into a sentry-box; on the outside it was fastened to three wooden posts by silken strings defended from the rain. This machine was the first that happened to be favoured by a visit from the ethereal fire. Dalibard himself was from home, but in his absence had intrusted the care of his apparatus to a person of the name of Coisier, on whose courage and industry he could depend: this person, having had all necessary instructions, was directed to call some of his neighbours, particularly the

curate of the parish, whenever there should be any appearance of a thunder-storm; at length the event arrived, and on Wednesday, the 10th of May, 1752, between two and three in the afternoon, Coisier heard a loud clap of thunder; he immediately ran to the sentry-box, and, in the presence of the curate and several neighbours, drew sparks from the conductor. A few days afterwards a successful repetition of the experiment was made by M. Delor at Paris.

These important and interesting experiments were of course repeated in almost every civilized country with variable success: in France a grand result was obtained by M. de Romas. (*Mém. des Sçavans Etrangers*, t. ii.) He had constructed a kite seven feet high, and three wide, which was raised to the height of 550 feet by a string with a fine wire interwoven through its whole length, to render it a better conductor. On the 26th of August, 1756, streams of light were darted from the string of this kite, of an inch in diameter, and ten feet long.

Considering the facility, and, at the same time, the danger of these experiments, it is curious that they have only in one instance been attended by a fatal result, namely, in the case of Professor Richman of Petersburg. He had constructed an apparatus for experiments on atmospheric electricity, which was entirely insulated, and with no contrivance for discharging it when too strongly electrified. On the 6th of August, 1753, he was examining the electricity of this apparatus in company with a friend, and whilst attending to an experiment, his head accidentally approached the insulated rod, and a flash immediately passed from it, through his body, and deprived him of life. A red spot was produced upon his forehead, his shoe was burst open, and a part of his waistcoat singed; his companion was for some time rendered senseless; the door of the room was split and torn off its hinges.

The discovery of the identity of lightning and electricity has not been without its practical results, among which we may especially enumerate the application of *Conductors* to buildings and ships, by which their safety during a thunder-storm is almost ensured. Franklin's original proposition for the purpose is that generally adopted; it consists in erecting a continuous metallic rod by the side of any building which it is intended to protect; the rod is *pointed* at each end, and extended above the highest part of the building at one extremity, the other penetrating deep into the earth, or in contact with water. In establishing this safeguard no other precautions are necessary than to have the top of the rod well and permanently pointed; and it is better of copper than iron, because the former does not so easily acquire a coating of rust, which, being a non-conductor, might possibly diminish its efficacy: it is sometimes well to subdivide the extremity into three or four points: and it should be secured to the side of the house in its descent, and penetrate so deep in the ground as always to be in free contact with a moist stratum of soil; if it ends in a deep well, so much the better. The diameter of the rod should be such as amply to secure it against being melted by a sudden and copious flash of electricity, for which purpose half an inch is fully sufficient; and if the roof is leaded, a broad strip of lead should connect it with the conductor. When a building is very extensive, it is as well to have a conductor at each end; and where a church-spire is to be protected, all clamps and bars

of metal, of any magnitude, used in its construction, should have a metallic connexion, by a strip of lead or otherwise, with the nearest part of the conducting-rod*. A small building containing very dangerous materials, such, for instance, as a powder-magazine, is perhaps most prudently defended from ignition by lightning, by placing the conductor within a few yards of the building, and elevated several feet above it; for this purpose it may be attached to a mast or signal-post in the vicinity.

Conductors for ships have usually been made moveable, with the intention of occasionally attaching them to the mast during dangerous storms; the consequence has been, that they have generally remained packed up below, and not in their place in the time of danger: they are also commonly made of chain, which is improper. Mr. Harris recommends fixed conductors, and has experimentally demonstrated their safety and value.

Persons not otherwise nervous or timid, often experience particular sensations of alarm and discomfort upon the approach of a thunder-storm, arising from some constitutional peculiarity, which perhaps renders them especially sensible of the influence of electricity upon the system. These and others are often led to inquire after the best means of safety upon such an occasion; the directions to be given are few and simple. If out of doors, trees should be avoided; and if, from the rapidity with which the explosion follows the flash, it should be evident that the electric clouds are near at hand, a recumbent posture upon the ground is the most secure. It is seldom dangerous to take shelter under sheds, carts, or low buildings, or under the arch of a bridge. The distance of twenty or thirty feet from tall trees, or houses, is rather an eligible situation, for should a discharge take place, such prominent bodies are most likely to receive it, and the less elevated objects in their neighbourhood may therefore escape uninjured. It is also right, during a thunder-storm, to avoid rivers, ponds, and streams of water, for they are good conductors, and the height of a human being when connected with them is likely to determine the course of the discharge. Within doors we are tolerably secure in the middle of a large carpeted room, or when standing upon a doubled hearth-rug. We should avoid the chimney, for the iron of and about the grate, the soot that lines it, and the heated and rarefied air that it contains, may conduct the lightning; upon the same principle, gilt mouldings, bell-wires, and extensive metallic surfaces of any description, are also in danger of being struck. In bed we are comparatively safe, for feathers and blankets are bad conductors, and we are consequently, to a certain extent, *insulated* in such situation. The cellar has been sometimes recommended as a particularly safe place of resort, and so it

* It not unfrequently happens that the iron or leaden water-pipes attached to houses act as excellent conductors, and supersede the necessity of any specific arrangement.

often is; but sometimes the basement story of a house is that which principally suffers: of this the cause is not very evident*.

We are often told that there is no danger if a certain interval of time can be counted between the flash and the report of the thunder; this is true enough; indeed, if we can count at all, we are safe. Where persons have been killed by lightning, it has generally come upon them so suddenly as to leave no time for precaution; though it must also be admitted that some have suffered from foolishly ridiculing the idea of danger, and wantonly exposing themselves to the storm, walking out to admire its grandeur, or insisting upon opening the windows to look out and observe it, or standing under a tree for shelter. A severe thunder-storm is always an awful and dangerous phenomenon; and while, on the one hand, it is the extreme of folly to neglect common precaution, or to ridicule those that are alarmed, it is, on the other, equally weak to give way to unfounded apprehension.

It is scarcely necessary here to describe a variety of amusing apparatus which has been constructed with a view to show the effects of lightning upon buildings, the means by which it harmlessly traverses good and continuous conductors, and the mischief which it produces when they are insufficient or interrupted. Models of houses, obelisks, powder-magazines, and ships, properly fitted up for these demonstrations, are sold by the philosophical instrument-makers.

The appearance of the heavens during a thunder-storm, the manner in which the clouds assemble, and attract and repel each other, the circumstance of their rising against the wind, and traversing the upper regions of the atmosphere in a variety of contrary directions, are phenomena which it is not difficult to explain by reference to those general laws of electricity which have been already sufficiently explained. Upon the same principles we account for the fringed appearance of a thunder-cloud, and for the ragged excrescences which it projects towards the earth, whilst its upper surface is generally smooth and well-defined. We sometimes observe that a number of such clouds of small dimensions coalesce into a larger one, moving swiftly in all directions, and darting

139

* When a tree is struck by lightning, it often happens that it is completely *barked*. This arises from the electricity taking that direction which best conducts it, and which is between the bark and the wood, where there is most sap and moisture. The bark, on such occasions, is often curiously spread round the tree in the form of a circle. When lightning strikes the ground it occasionally indurates and fuses the substances through which it passes. What are termed *sand-tubes* appear to be formed by the passage of lightning through a sandy soil which it fuses in its passage. They are coated with agglutinated sand, and are about the twentieth of an inch thick, very hard, and furrowed upon the exterior. The annexed cut represents one of these tubes, as described by Mr. Irton (*Geol. Trans.*, 1812). In one part of its passage (at *a*) the electric fluid met with a bed of pebbles which were fused into a mass.

flashes from one to the other, whilst the wind rises and often blows in squalls; the lightning is more frequent as the clouds aggregate, and a great expanse of the heavens often appears in an almost continuous blaze of light. The thunder, at first rumbling in the distance, now approaches with various roaring and rattling sounds, and the rain often falls in torrents.

If we watch a severe thunder-storm from the beginning to the end, we observe a singular variety in the appearance of the flashes: the scene is sometimes rendered awfully magnificent by their brilliancy, frequency, and extent, darting sometimes in broad and well-defined lines from cloud to cloud, and sometimes shooting towards the earth: they are often zig-zag and irregular, and sometimes are said to appear as a large and rapidly-moving ball of fire, an appearance usually designated by the uninformed, a *thunder-bolt*, and erroneously supposed to be attended by the fall of a solid body. The report of the thunder is modified, according to a variety of circumstances, depending partly upon the situation of the observer, the nature of the country, and the extent of air which it traverses. Sometimes it sounds like the firing of many muskets at a short distance off; sometimes like the clattering of loose boards upon each other, or the sudden emptying of a large cart-load of paving-stones: in these cases it usually quickly follows the lightning, and is near at hand: when more distant, it rumbles and reverberates, at first with a loud report, gradually dying away and returning at intervals, or roaring like the distant discharge of heavy artillery. In accounting for these phenomena it must be recollected, that the passage of electricity is infinitely rapid; a discharge through a circuit of many miles has been experimentally proved to be instantaneous; the motion of light is similarly rapid, and hence the flash appears momentary, however great the distance through which it passes. But with *sound* the case is very different; it is infinitely slower in its progress, moving only at the rate of about twelve miles in a minute (p. 189). Now supposing the lightning to pass through a space of some miles, the explosion will be first heard from the point of the air agitated nearest to the spectator; it will gradually come from the more distant parts of the course of the electricity; and last of all will be heard from the remote extremity; and the

different degrees of the agitation of the air, and likewise the difference of the distance, will account for the different intensities of the sound, and its apparent reverberations and changes. If the observer be equidistant, or nearly so, from every part of the flash, he will hear a single crash: this will happen if we suppose *a*, (fig. 140), to represent the observer, and *b* the direction of the flash; which is here passing in an uniform line, as it is sometimes observed to do from a small and highly-charged cloud.

The common progress of lightning is, however, much less regular, (fig. 141,) and may be represented by the zig-zag lines *b c*, the spectators

standing at *a*, in which case the sound will first come to them from the nearest point, and will then seem to recede and again to approach, rumbling irregularly as the sound arrives from the different portions of traversed air, some nearer and some further from them, until it is at length lost in the distance. This

irregularity in the passage of the electric discharge is sometimes so considerable, that the thunder is actually lost to the ear at one moment, and heard again at another, and this three or four times successively in the same clap.

There was at one time a controversy among electricians respecting the relative advantages of points and balls in the construction of conductors; but, consistently with Dr. Franklin's original recommendation, points are now universally adopted. Dr. Franklin suggested an experiment in proof of his opinion, which consisted in attaching to the prime conductor of the electrifying-machine one or more large flocks of cotton, so as to resemble electrified clouds. When a point is made to approach these, they collapse and recede, and quickly lose their electricity: when, on the other hand, they are approached by a ball, they are attracted towards it, and the charge is more slowly dissipated.

Of the cause of atmospheric electricity we are nearly ignorant: it is true that many changes which are continually going on upon the earth's surface, and in the surrounding atmosphere, are of such a nature as are known to disturb the electric equilibrium; evaporation; change of state or form in the varieties of matter; changes of temperature; chemical action; all these are sources of electrical excitation; but still they can hardly be adduced as offering a satisfactory explanation of the enormous electrical accumulation which a thunder-storm evinces. That sudden, violent, and extensive chemical and mechanical changes in the forms and states of matter, are causes by which electricity is often copiously manifested, is shown by the flashes of lightning that accompany volcanic eruptions, and by the highly electric state of the surrounding atmosphere that attends them.

Another natural phenomenon, which may be referred to electric excitation, is the *waterspout*; it appears to result from the electric attraction of a mass of vapour or cloud acting upon the water beneath: it first causes the appearance of a hillock in the ocean; the water is then drawn up in a column towards the cloud, and the cloud and rain are attracted towards the water.

It occasionally happens that volcanos suddenly break forth in the sea, and sometimes in very deep water; and they are attended by thunder,

lightning, and waterspouts. Of such an eruption a curious account is given by Captain Tillard in the *Philosophical Transactions*, and of its general appearance and effects some notion may be formed from the following wood-cut. In June, 1811, Captain Tillard, on approaching the island of St. Michael, observed several columns of smoke rising in the horizon, which proved to issue from a marine volcano about a mile off the north-west end of the island, whither he proceeded more nearly to inspect the phenomena. "Imagine," he says, "an immense body of smoke rising from the sea, the surface of which was marked by the silver rippling of the waves, occasioned by the slight and steady breezes incidental to those climates in summer. In a quiescent state it had the appearance of a circular cloud, revolving on the water like a horizontal wheel, in various and irregular involutions, expanding itself gradually on the lee side, when suddenly a column of the blackest cinders, ashes, and stones, would shoot up in the form of a spire, rapidly succeeded by others, each acquiring greater

142

velocity, and breaking into various branches, resembling a group of pines; these again forming themselves into festoons of white feathery smoke. During these bursts, the most vivid flashes of lightning continually issued from the densest parts of the volcano, and the columns rolled off in large masses of fleecy clouds, gradually expanding themselves before the wind in a direction nearly horizontal, and drawing up a quantity of waterspouts, which formed a striking addition to the scene. In less than an hour a peak was visible, and in three hours from the time of our arrival, the volcano then being four hours old, a crater was formed, twenty feet high, and from four to five hundred feet diameter."

The account then goes on to state, that the eruptions were attended by a noise like the firing of cannon and of musketry intermixed, as also with shocks of earthquakes sufficient to throw down a large part of the cliff on which the observers stood; it is, however, principally to the *lightning* and to the *waterspouts* that I would here direct the reader's attention. Captain Tillard afterwards visited the volcanic island: it was eighty yards high; its crater upon the level of the sea was full of boiling water; it was about a mile in circumference, and composed of porous cinders and masses of stone.

The *Aurora Borealis* is another natural phenomenon, probably connected with or dependent upon electricity; its appearances, indeed, may be, to a certain extent, imitated by artificial electricity, which, when it passes through rarefied air, exhibits a diffused luminous stream, having

much resemblance to the characteristic appearances of the northern lights. "There is," says Mr. Singer, "the same variety of colour and intensity; the same undulating motions, and occasional coruscations; the streams exhibit the same diversity of character, divided at one moment into minute ramifications, and at another beaming forth in one body of light, or passing in distinct broad flashes; and when the rarefaction is considerable, various parts of the stream assume that peculiar glowing colour which occasionally appears in the atmosphere, and is regarded by the uninformed observer with astonishment and fear."

The affections of the magnetic needle and of the electrometer during the appearance of the Aurora, as well as other phenomena connected with it, have been noticed by several eminent philosophers. Halley and Dalton directed the attention of meteorologists to this subject; and, more lately, Captain Franklin has added material information upon it (*Journey to the Shores of the Polar Sea*, Appendix); it has also been accurately described by Captain Parry, who had ample opportunities of observing it in great perfection and splendour, during his perilous voyages in search of a north-west passage from the Atlantic to the Pacific. In this country the Aurora Borealis is rarely seen in perfection. On the 13th of October, 1792, it appeared in great brilliancy; and an account of it, from which the following extract is taken, has been given by Mr. Dalton in his *Meteorological Essays*. The reader may also consult the description given by Mr. Kendall of the Aurora which appeared here in October, 1829 (*Quarterly Journal of Science*).

"Attention was first excited," says Mr. Dalton, "by a remarkably red appearance of the clouds to the south, which afforded sufficient light to read by at eight o'clock in the evening, though there was no moon nor light in the north. From half-past nine to ten there was a large, luminous, horizontal arch to the southward, and several faint concentric arches northward. It was particularly noticed, that all the arches seemed exactly bisected by the plane of the magnetic meridian. At half-past ten o'clock, streamers appeared very low in the south-east, running to and fro from west to east; they increased in number, and began to approach the zenith, apparently with an accelerated velocity; when, all on a sudden, the whole hemisphere was covered with them, and exhibited such an appearance as surpasses all description. The intensity of the light, the prodigious number and volatility of the beams, the grand intermixture of all the prismatic colours in their utmost splendour, variegating the glowing canopy with the most luxuriant and enchanting scenery, afforded an awful, but, at the same time, the most pleasing and sublime spectacle in nature. Every one gazed with astonishment, but the uncommon grandeur of the scene only lasted about one minute; the variety of colours disappeared, and the beams lost their lateral motion, and were converted into the flashing radiations. Notwithstanding the suddenness of the effulgence at the breaking out of the Aurora, there was a remarkable regularity in the manner; apparently a ball of fire ran along from east to west with a velocity so great as to be barely distinguishable from one continued train, which kindled up the several rows of beams, one after another; these rows were situate before each other with the exactest order, so that the lases of each row formed

a circle crossing the magnetic meridian at right angles: and the several circles rose one above another, so that those near the zenith appeared more distant from each other than those near the horizon, a certain indication that the real distances of the rows were nearly the same." This Aurora continued for several hours; there were many meteors, or falling stars, seen at the same time, but they appeared to be below, and unconnected with the Aurora.

During Captain Parry's voyage, he had numerous opportunities of witnessing the Aurora in uncommon magnificence. The following is an abstract of his description of its appearance on the 14th of December, 1821. (*Second Voyage for the Discovery of a North-West Passage*, p. 142). "The Aurora began to show itself as soon as it was dark. Innumerable streams of white and yellowish light occupied the heavens to the southward of the zenith, being much brighter in the south-east, from whence it often seemed to emanate. Some of these streams were in right lines, others crooked, and waving in all sorts of irregular figures, moving with inconceivable rapidity in various directions. Among them might frequently be observed shorter bundles of rays, which, moving even with greater velocity than the rest, have acquired the name of 'merry dancers.' In a short time the Aurora extended itself over the zenith about half way down to the northern horizon, but no further, as if there was something in that quarter of the heavens which it did not dare to approach. About this time, however, some long streamers shot up from the horizon in the north-west, which soon disappeared. While the light extended over part of the northern heavens, there were a number of rays assuming a circular or radiated form near the zenith, and appearing to have a common centre near that point, from which they all diverged. The light of which these were composed appeared to have inconceivably rapid motion in itself, though the form it assumed, and the station it occupied in the heavens, underwent little or no change for perhaps a minute or more. This effect is a common one with the Aurora, and puts one in mind, as far as its motion alone is concerned, of a person holding a long ribbon by one end, and giving it an undulatory motion through its whole length, though its general position remains the same. When the streams or bands were crooked, the convolutions took place indifferently in all directions. The Aurora did not continue long to the north of the zenith, but remained as high as that point for more than an hour; after which, on the moon rising, it became more and more faint, and at half-past eleven was no longer visible.

"The colour of the light was most frequently yellowish-white, sometimes greenish, and once or twice a lilac-tinge was remarked, when several strata appeared as it were to overlay each other by very rapidly meeting, in which case the light was always increased in intensity. The electrometer was tried several times, and two compasses exposed upon the ice during the continuance of this Aurora, but neither was perceptibly affected by it. We listened attentively for any noise which might accompany it, but could hear none, but it was too cold to keep the ears uncovered very long at one time. The intensity of the light was something greater than that of the moon in her quarters. Of its dimming the stars there cannot be a doubt. We remarked it to be in this respect like

drawing a gauze veil over the heavens in that part, the veil being most thick when two of the luminous sheets met and overlapped. The phenomenon had all the appearance of being full as near as many of the clouds commonly seen, but there were none of the latter to compare them with at the time."

My object in the above extracts has been to give an account of those appearances of the Aurora which seem to connect them with electricity, and though Captain Parry neither observed the electrometer nor the magnetic needle to be influenced, Captain Franklin (*Journey to the Shores of the Polar Sea*, App.) remarked them both to be affected. Nairne, Cavallo, and others, have described a peculiar hissing noise as one of the accompaniments of the Aurora; and Dr. Halley, in his description of a remarkable Aurora, (*Phil. Trans.*, vol. xxx.,) ascribes its production to the same influence as that which produces magnetism; and Beccaria conceived the phenomena of magnetism to be dependent upon a circulation of the electric fluid from north to south, originating from several sources in the northern hemisphere.

All *meteors* were at one time considered as derived from electricity; but the showers of stones by which many of them are accompanied show that they must often be ascribed to other sources. What are termed *falling stars* are supposed by some to be of electric origin. These vary a little in size and colour, moving in various directions, but chiefly appearing to shoot towards the earth. They are most common in those states of the atmosphere favourable to electric accumulation, especially on clear frosty nights, or when the sky is cloudless and the wind easterly; in the clear intervals of a showery evening, and on summer nights, when well-defined clouds are floating in a serene atmosphere. They are also common during the prevalence of the Northern Lights, appearing then to be lower than the Aurora; and from their comparative brilliancy, probably moving through a more dense medium.

The appearance of a shooting star may be imitated by discharging a Leyden jar through an imperfectly-exhausted glass tube, or air-pump receiver. The tube should be capped with brass at both ends, and about three feet long and an inch in diameter; if too perfectly exhausted the spark passes in a divided and pale stream of light, but on admitting a little more air it traverses in the form of a bright flash or spark.

It appears from the best-conducted experiments on atmospheric electricity, that in the usual state of the atmosphere it is generally *positive*, but that it frequently changes to *negative* upon the first appearance of rain, snow, or hail. The approach of clouds often influences the electricity of the conductor, so as to produce alternations of the two electricities. There appears, as might be expected, to be a greater accumulation of electricity in the atmosphere during the presence of regular thunder-clouds, than at any other period; a driving fog accompanied by small rain, a fall of snow, and a smart shower on a hot day, are also attended by powerful signs of electric excitation. Hot weather succeeding wet, or wet weather following a series of dry days, are also favourable circumstances for the generation of atmospheric electricity. The atmosphere is least electrical during the prevalence of north-easterly winds, and in that state which produces a disagreeable sensation of dryness and of cold

without a corresponding depression of the thermometer. It has also been remarked, that the usual positive electricity is weakest during the night; that it increases with the sun-rise; decreases toward the middle of the day, and again increases as the sun declines; it then again diminishes and remains feeble during the night; it would, therefore, seem probable that the electricity of the atmosphere is influenced by the same causes that modify the distribution of moisture.

§ 11.—GALVANISM AND VOLTAIC ELECTRICITY.

WE have now acquired such preliminary information upon the subject of electrical excitation, and of the phenomena exhibited by electrified bodies in general, as may enable us to proceed to other cases of the evolution of this singular agent. In the mean time, we may observe, that scarcely any change in the general state of matter is unattended by a disturbance of the electrical equilibrium. Thus, the disruption of solid bodies, changes of temperature, changes of form, are all sources of electricity; breaking up a mass of sugar, tearing asunder the plates of mica, cleaving a piece of dry wood, heating certain minerals, evaporating liquids, and condensing vapours, may be cited as instances; but, of all such changes, those resulting from *chemical* action are apparently the most important, and are immediately connected with those curious cases of the manifestation of electricity, commonly described under the terms *galvanism* and *voltaic electricity*.

In the year 1790, Galvani, of Bologna, discovered that the transmission of a small quantity of electricity through the nerves of a recently killed animal, produced spasmodic convulsions of the muscles: and if the sciatic nerve of a frog be laid bare, and touched with a piece of *zinc*, whilst, at the same time, the muscle is touched with *gold*, similar effects to those of electricity were produced whenever the metals were brought into *contact*, or connected together by *conductors* of electricity: if non-conductors were used to connect the metals, no spasm ensued. Cold-blooded animals retain this kind of excitability longer after death than others, and they are affected by states of electricity so feeble as not to be indicated by the most delicate electrometers. A feeble spark, or the most trivial charge of a Leyden phial, produce analogous effects. These facts soon attracted considerable attention, and were followed up with much diligence and curious results.

Frogs are the most convenient and susceptible animals for these experiments; but when they cannot easily be obtained others may be substituted. The annexed sketch (fig. 143) represents the legs of the frog prepared for galvanic experiments: the skin is removed, and the crural nerves *a a* are then easily found, by gently separating the muscles: *b* is a silver wire passed under both

the nerves, for the convenience of ensuring metallic contact: if the legs be now folded up and placed upon a plate of zinc, convulsions are produced whenever a metallic communication is made between the wire *b* and the zinc plate. A similar experiment may be made with a live flounder, which may generally be procured at the fishmonger's. Place the flounder in a plate upon a slip of zinc, and put a shilling upon its back; then, with a piece of wire connected with the zinc, make occasional contacts upon the shilling, and at each contact strong muscular contractions are produced. According to Dr. Ure (*Dictionary*, Art. GALVANISM), the degree of muscular contraction depends upon the direction of the electric current, and is greater when the zinc touches the nerve, and the copper or silver the muscle, than when this order is reversed*.

In these experiments, if the separate pieces of metal be of the *same* kind, no effects are observed: to produce them, two *different* metals are requisite, and these must be in contact; and those metals which are most difficultly acted upon by acids, opposed to those which are easily soluble, form, in general, the most powerful combination. Thus, gold and platinum produce scarcely any effect; but gold, or platinum, or silver, opposed to iron, tin, or zinc, are very effectual. This part of the subject will, however, be more explicitly inquired into afterwards.

There are many other experiments and illustrations relating to this subject, two or three of which may be here noticed. If a piece of silver be placed *upon* the tongue, and a piece of zinc *under* it, no effect is observed whilst the metals are kept apart; but, if their ends be brought into contact, we immediately perceive a saline taste, and a peculiar sensation, somewhat resembling a very slight electrical shock; sometimes, also, when the surface of the metals is extensive, a flash of light appears to pass before the eyes. This latter effect may be more certainly produced by placing one metal between the upper lip and the gums, and the other upon the tongue, and bringing their ends together as before.

To account for these, and similar effects, Galvani supposed that the nerves and muscles of animals were in opposite electrical states, and that the spasms were produced in consequence of their annihilation by the metallic conductor. But this hypothesis was controverted by Volta, who showed that contractions might be excited by the application of two different metals, but not by one only, and referred the effect to the *electromotive power of the different metals*.

When two dissimilar metals were brought into contact, he found that very feeble electrical states were developed in them. When an insulated plate of zinc was brought into contact with one of silver or copper, the former was found to be in a feebly *positive* state, and the latter

* The phenomena mentioned in the text have given rise to various experiments in reference to the relation between electricity and the vital functions; among these researches, those contained in Dr. Wilson Philip's communications to the Royal Society, and in his *Experimental Inquiry into the Laws of the Vital Functions*, are the most precise. Attempts have also been made, to apply

the stimulus of electricity in cases of suspended animation, from suffocation and drowning. Dr. Ure's interesting account of the effects of galvanism upon the body of a criminal, executed at Glasgow, deserves the attentive perusal of those who are concerned in these medical and physiological applications of electricity; but the subject is too extensive to be entered upon here in detail.

negative, as if a minute portion of electricity had passed *from* the least to the most oxidizable metal. To this transfer, or disturbance of electricity, Volta referred the convulsive motion of the frog's limbs, considering the nervous irritability of the animal as highly susceptible of such influence, and as operating as an extremely sensible electroscope; and the production of similar convulsive twitches by common electric sparks and shocks, was adduced in favour of this opinion.

The following experiment has also been referred to, as a case of electrical excitation, depending upon the *contact* of dissimilar metals:—Place a large plate of metal upon the cap of the gold-leaf electrometer, and sift *zinc* filings upon it through a *copper* sieve, held by a glass handle: the leaves will diverge with *positive* electricity, and the sieve will acquire a *negative* state. Repeat the experiment, substituting a *zinc* sieve and *copper* filings, for the copper sieve and zinc filings, and the divergence of the electrometer will be *negative*, the sieve being *positive*. But when we recollect by what slight causes electricity is sometimes made evident, it becomes a question whether mere *contact* is the only source of its development in these and the preceding cases; whether friction, change of temperature, or even, ultimately, chemical action, may not interfere.

In reference, however, to these cases of supposed electrical excitation by the contact of different metals, it is found that the most oxidizable metal is always *positive*, in relation to the least oxidizable metal, which is *negative*, and the more opposite the metals in these respects, the greater the electrical excitation; and if the metals be placed in the following order, each will become *positive* by the contact of that which precedes it, and *negative*, by the contact of that which follows it; and the greatest effect will result from the contact of the most distant metals. Platinum—Gold—Silver—Mercury—Copper—Iron—Tin—Lead—Zinc—Potassium. Here we have strong presumptive evidence in favour of a chemical cause as the source of electricity, for it is not produced by the most dissimilar *conductors* either of heat or of electricity, but by those which are most opposed in the facility with which they are acted upon by the generality of chemical agents; and it will be moreover found that, upon this chemical action, the direction of the current entirely depends.

Linked as it were with these electrical changes, are certain chemical actions, of which the following are simple instances:—

1. Place a wire of *silver* and one of *zinc* in dilute sulphuric acid, taking care that they do not touch each other; the zinc only will be acted upon by the acid, and the silver remains perfectly inert. Now, bring the upper ends of the wires *into contact*, and the silver will immediately become active: a stream of gas will issue from both wires.

2. Fill a wine-glass with a weak solution of sulphate of copper (*blue vitriol*), and place in it a small plate of clean *iron*, and one of *silver*: the iron will soon acquire a cupreous coating, but the silver remains bright until brought *into contact* of the iron, when it immediately becomes plated with copper.

3. When the *copper* sheathing is affixed to the bottom of ships with *iron* nails, their heads soon corrode and give way, but when the nails are also of copper, no such destructive effect is observed: *iron* railings are

apt to be decayed and dissolved when cemented into stone-work by *lead*; the effect is chiefly observed at the point of junction of the two metals: an *iron* pump put into a *leaden* cistern, or the junction of *iron* and *leaden* pipes, causes the corrosion of both the metals, but first and chiefly of the *iron*: when *copper* is immersed in sea-water it is soon corroded, and gives it a green tint; but if a piece of *iron* or *zinc* be in contact of the copper and the water, no such destruction ensues, the copper being *protected* by the *iron*.

Before we consider these and other *electro-chemical* effects in detail, I shall describe an instrument which will serve to connect them with the phenomena of attraction and repulsion, already adverted to, and to explain the direction of the electric current in these cases of excitation: it is called from its inventor, *De Luc's electric column*. It consists of a number of alternations of two metals, with interposed paper; for this purpose thin paper covered with *silver* leaf may be used, punched out into circular discs of about half an inch diameter, and alternating with similar discs of thin *zinc* foil, so arranged that the same order of succession—namely, *zinc*, *silver*, *paper*, *zinc*, *silver*, *paper*, &c., may be kept up throughout. About five hundred such alternations will be required to produce an active column, and they are most conveniently placed in a suitable glass tube, perfectly clean and dry within, and surmounted at each end with a brass cap, perforated by a screw, by which the plates may be pressed together, and which also serve as the poles of the arrangement; the screw at one end being in contact with the *zinc* plate, and that at the other with *silvered* paper*.

If we hold this column by one of its brass caps, and with the other, touch the cap of the gold-leaf electrometer, a divergence will be communicated to the leaves, which will be found to be *positive* from one end, and *negative* from the other of the arrangement; that end of the column to which the *zinc* surfaces incline, is usually called the *positive* extremity, or pole, and that to which the *silver* plates incline, the *negative* extremity.

If we place the column with each of its extremities in connexion with the electrometers, as represented in the annexed cut (fig. 144), one of the instruments will be *positively*, and the other *negatively* diverged; and on making a direct communication between the two electrometers by a metallic wire, the divergence ceases, but again ensues soon after such communication is broken.

It will be found convenient in experiments with this column to employ two, each containing 500 discs; these may be united end to end,

* Analogous arrangements were made by Hachette and Desormes with pairs of metallic plates, separated by layers of paste mixed with salt; and by Zamboni,

who used discs of paper, gilt or silvered on one side, and covered on the other with a mixture of black oxide of manganese and honey.

so as to form one continuous arrangement. If we examine into the state of the electricity thus excited, we shall find it resembling that of a conductor under induction: that is, there is a positive and a negative pole, and a central point, which exhibits no electricity; upon making a communication between either end of the column and the ground, the electricity of the opposite end becomes proportionally exalted.

In the experiments we are now about to describe it will be found convenient to employ an electrometer, in which each gold leaf is separately insulated, and so arranged as to admit of their being brought nearer to, or carried further from each other. Such an instrument is represented in fig. 145, where *a* is a glass cylinder mounted upon a brass or wooden base, *b*; the cover, *c*, is a thin piece of dry and varnished wood, with a slit in it, in which the glass tubes, *d d*, slide backwards and forwards, and through which, brass wires pass, with a slip of gold leaf attached to each of their lower extremities.

If we now, having duly adjusted the distance between the gold leaves, bring the *zinc* ends of the columns in contact with each of the wires to which they are attached, the leaves *repel* each other; the *silver* ends produce a similar effect: but, if one of the gold leaves be connected with the *zinc* end, and the other with the *silver* end of the column, they *attract* each other; and having thus, by contact, annihilated their opposite electrical states, they separate for a moment, and then again attract and separate as before, a kind of perpetual motion being kept up between the leaves in consequence of the successive electrical charges communicated to them by the column. Upon this principle a variety of instruments have been constructed, under the name of *perpetual motions*: thus, a small clapper may be kept constantly vibrating between two bells; or a light pendulum between two conducting surfaces; and these motions continue as long as the column retains its electric activity, which is often for months or years.

If one end of De Luc's column be connected with the *interior*, and the other with the *exterior* of a Leyden jar, the jar will receive a charge; its knob will affect a gold-leaf electrometer, and on discharging it by a wire, a very small spark will be observed. To obtain this spark, or any luminous appearance, without the intervention of the jar, requires a very extensive series of the metallic alternations.

It will be observed, in regard to this instrument, that its electrical excitement is chiefly that of intensity, and that after its discharge a sensible time intervenes before its power is renewed: its electricity is *apparently* independent of chemical action, and has therefore been considered referable only to the *contact* of the metals. In favour of this opinion it has been urged that whenever any chemical action is apparent in it, its electrical effects cease, as when the zinc or silver become tarnished, or the intervening papers more than ordinarily damp; but it is also rendered inactive by drying the papers so as to deprive them of their hygrometric moisture, and it is said that in the course of years the zinc becomes evidently corroded. It was always presumed that no chemo-

electrical effects could be obtained from these piles, but Mr. Gassiot has succeeded in decomposing iodide of potassium by a column of 10,000 series upon Zamboni's construction. (*Phil. Trans.*, 1839, p. 191.)

What is commonly called "a simple galvanic circle" is formed by partially immersing *two different metals in a dilute acid*, and making a communication between them, either by direct contact, or by some perfect

conductor; one of the metals should be easily, and the other difficultly, or not at all, acted upon by the liquid, and the more opposite the metals are in these respects, the more powerful are the electrical effects observed. In fig. 146, z represents a plate of zinc, and s is one of silver, partly immersed in very dilute sulphuric acid, and in contact at their upper ends; by such arrangement a current of electricity appears to be put in motion, passing from the zinc to the acid, from the acid to the silver, and from the silver again to the zinc, as shown by the

direction of the darts. Or the arrangement may be modified, by immersing the plates separately in the acid, and connecting them by wires, as in fig. 147: the circuit will thus be extended, but the electrical current will be

found moving in the same direction, from the zinc towards the silver, and through the wires from the silver to the zinc, in the direction represented by the arrows. In thus completing the circuit by wires, the electric current may conveniently be transferred through fluid and other bodies, and the circuit may be broken and restored at pleasure, by alternately separating and renewing the contact of the wires at A. It will be observed, that in consequence of the direction of the electric current in this arrangement, the wire B, connected with the silver plate, is conveying electricity to the wire C, united to the zinc plate. Hence B is considered as *positive*, and C as *negative*.

This arrangement may be modified by interposing a few folds of blotting paper, or a piece of flannel dipped in the acid, between the plates, instead of immersing them into the acid itself; or, as in the annexed sectional diagram (fig. 148), the silver or copper plate may itself form the vessel for containing the acid, s representing the wire connected with the cup, and z that with the zinc plate, care being taken that the plate is nowhere in *metallic* contact with the cup.

Another useful modification of this form of apparatus is the following:—c is a cup, composed of two cylinders of sheet-copper, placed one within the other, and closed at bottom, to contain dilute acid: z is a zinc cylinder with a few pieces of cork attached to it, so as to prevent its touching the sides of the cup a, when introduced into its

place between them: *b b* are small copper cups, soldered to conducting-wires, and containing a little mercury, for the purpose of conveniently making and breaking the circuit*.

To understand the peculiar phenomena presented by these and similar arrangements, it will be necessary to refer to the important distinctions between electricity of *tension*, accumulated upon surfaces, and manifesting itself by attractions and repulsions, and by discharges passing through air; and electricity in *motion*; the *intensity* of the electricity produced by these simple circles is either null, or so trifling as to require extremely delicate instruments, or electrosopes, to render it sensible; but its quantity is great; and, accordingly, if we make it traverse a very fine metallic wire, placed between the wires *A*, fig. 147, or *z* and *s*, fig. 148, or between the cups *b b*, fig. 149, the wire will become hot, and often ignited; a spark will pass between two fine charcoal points when brought

* It may be well here to allude to the phenomena by which the presence and direction of the electric current are proved. In examining the electricity of the common electrical machine, it has been stated that where the positive and negative conductors are made to communicate by a wire, a current of electricity traverses that wire, and is presumed so to circulate from the positive to the negative side. In the arrangements (figs. 146 and 147) the electricity generated by the action of the dilute acid upon the zinc plate, passes across the liquid to the silver plate, and circulates in the direction of the arrows. In the following diagram the current of the machine is compared with that of the simple galvanic circle. *A* represents the excited cylinder, *N* the rubber, *P* the prime conductor, *w* a metallic wire through which the electric current passes in the direction of the darts; *z* a zinc plate, *s* a silver plate, immersed in dilute acid, and giving rise to a current, the direction of which corresponds with the former. We can now, in either of these arrangements, get evidence of the current, by one or all of the following indications. 1. By heat, as when the metallic circuit, being interrupted, the spark fires ether; or when a very fine platinum wire is interposed between the ends of the thicker wire *A* of fig. 147. 2. By light, as seen in the spark, and the heating of the small wire red hot. 3. By the magnetic properties conferred upon the wires during the passage of the electric current, as shown by the galvanometer,

which will be more fully described afterwards. 4. By the chemical effects of the current when made to traverse certain electrolytes. The further explanation of all these phenomena will be given as we proceed. In this diagram

c represents the direction of the thermo-electric current, *D* that of the marked or north pole of a magnet round the electric current; and *E* that of the electric wire round the magnetic pole; of these also, further explanation will be given in the sequel.

into contact; the *galvanometer* will be powerfully deflected; and certain compound substances, made part of the circuit, will be decomposed: here, then, we have, as evidences of the *current* of electricity above alluded to the production of heat and light, and of magnetic and chemical effects.

There are two circumstances which materially interfere with the *quantity* of electricity put into motion by these arrangements. The one is the *size of the plates*, and the other the *nature and strength of the interposed acid or liquid*; or, in other words, the nature and energy of the *chemical action*. By increasing the superficial extent of the plates, the extent of chemical action is increased, and the *quantity* of electricity proportionately augmented; and in the case of zinc and dilute sulphuric acid, the more rapidly the zinc is oxidized, and the oxide removed, so as to expose successive new surfaces to the agency of the intervening fluid, the greater is the quantity of electricity which traverses the circuit. Indeed, the heating effects of a single pair of plates of great extent of surface is such, that instruments so constructed have been termed *calorimeters*. In an arrangement for this purpose, made under the direction of Mr. Pepys, at the London Institution, (*Phil. Trans.*, 1823,) a sheet of zinc and one of copper were coiled round each other, each being 60 feet long and 2 wide; they were kept asunder by the intervention of hair-ropes, and suspended over a tub of acid, so that by a pulley they could be immersed and removed.

In all these cases, however, the *intensity* of the electricity remains the same, or nearly the same, and, to increase it, we resort to increase of the *number* of the alternations of metals and acid; this constitutes "a compound galvanic circle," and leads to the arrangement originally devised by Volta, and hence termed the *VOLTAIC pile* or *apparatus*. Volta's original pile consisted of a number of plates of two different metals, alternating with moistened flannel or pasteboard, and arranged in regular order of succession. Zinc and copper are the metals in general use: zinc and silver, or zinc and platinum, would furnish a more active series, but the use of the latter metals, in extensive combinations at least, is prohibited by their expense.

To construct the voltaic pile, take from thirty to fifty plates of copper, and as many of zinc, from two to four inches square, and place them in regular order, with an intervening piece of wet flannel of the same size, well soaked in a solution of common salt in water, taking care that the regular succession of *copper, zinc, flannel-copper, zinc, flannel*, is kept up through the series. Having made this arrangement, connect a wire by *perfect metallic contact* with the lowest, or copper, and a similar wire with the uppermost, or zinc plate, having previously slipped a small piece of glass tube upon the wires, to serve as an insulating handle; then, on bringing the upper wire in contact with the condensing electrometer, it will diverge the leaves *positively*, and the lower wire *negatively*, and the same general phenomena will be observed as in De Luc's column. If the fingers be thoroughly moistened, by rubbing them with salt and water, so as in some measure to overcome the non-conducting power of the cuticle, a slight shock will be perceived on touching the extreme wires with each hand: a spark is rarely observed, even in a dark room. But if we now substitute a solution of salt soured by sulphuric acid, for moistening the

intermediate flannel, we shall not observe any material change in the mere electrical power of the pile as indicated by the affections of the electrometer: the shock will be a little more powerful; and a *spark* will be perceived, on bringing the poles together, more especially brilliant when taken between two points of well-burned charcoal attached to the wires from the top and bottom of the pile. Also, if we now bring the wires from the extremities of the pile (which for this purpose should terminate in strips of platinum) near each other, in a glass of acidulated water, gas will be extricated at each conductor.

In the construction of the voltaic pile, as just described, much inconvenience results from the method of arrangement, when the plates are very numerous; and the weight of the upper part of the pile presses the moisture out of the lower part, and renders it comparatively inactive. To obviate this, each pair of plates is sometimes soldered together, and cemented in regular order, into a well-seasoned mahogany trough, as in fig. 151; and the intervening cells, which are about a fourth of an inch wide, are filled with water, or other proper liquid, by which the arrangement is rendered active. The apparatus thus constructed is easily filled and emptied, and may be kept clean by rinsing it out with water, after use. A wire, in contact with the last zinc plate, and with the last copper plate, enables us, as before, to complete the circuit.

151

Another form of this apparatus, called by Volta the "*Couronne des tasses*," consists in arranging a row of small glasses or cups, (figs. 152,

153,) containing a very dilute sulphuric acid (or other proper liquid), in each of which is placed a plate or wire of platinum, silver, or copper, and one of zinc, not touching each other, but so connected, that the zinc of the first glass may be in metallic contact or communication with the silver or copper of the second, and the zinc of the second glass with the silver or copper of the third, and so on throughout the series, as shown in the annexed cuts.

152

153

By arrangements of this kind, we can see what happens in each cell of the apparatus; and it will be observed, that when the extreme wires or poles are *in contact*, and a current of electricity therefore passing through the arrangement in the direction of the arrows, each wire or metallic surface immersed in

the liquid is active; whereas, when the connexion between the poles is broken, the silver and the copper cease to evolve gas. In other respects, the general properties of the apparatus thus arranged, resemble those of the other forms above described.

Another good form of the voltaic apparatus is constructed upon similar principles: it consists of a trough of earthenware, with partitions of the same material (fig. 154). The plates, of copper and zinc, are soldered together at one point only, and each united pair of plates is so arranged as to enclose a partition between them; consequently, there is in each cell, a copper plate connected with the zinc of an adjoining cell, and so on, in regular succession; and the connecting piece of the last copper plate is elongated, so as to enable it to dip into the first cell of the next trough, when several such troughs are placed in rows endways to each other; it is there opposed to the ensuing zinc plate of another set, and so on.

The plates are attached to a slip of baked wood, so that the whole may at once be lifted into or out of the cells. This construction, originally suggested by Dr. Babington, has many advantages; it admits the fluid to remain in the trough, while the action of the plates may be suspended at pleasure, by lifting them from the cells; when the plates are corroded or injured, they are also easily replaced. Where many of

these troughs are employed, so as to constitute a powerful battery, it is necessary to be extremely attentive to the regular order of succession throughout the series; if any plates are misplaced, or any single set reversed, a great diminution of effect is the consequence. Much care must also be taken respecting the communications between the troughs, to prevent the accidental displacement of any of the junction-plates. It is well to be provided with a few spare pairs of plates attached to each other by a sufficiently long copper strap, for the purpose of uniting the troughs, where their arrangement requires that they should be placed at angles to each other.

A considerable improvement in the construction of this apparatus was suggested

in the year 1815 by Dr. Wollaston. It consists in extending the copper plate, so as to oppose it to both surfaces of the zinc, as shown

in the annexed sketch (fig. 155), where A represents the bar of wood to which the plates are screwed; BB the zinc plates connected as usual with the copper plates c c, which are doubled over the zinc plates, and opposed to them upon all sides, contact of the surfaces being prevented by pieces of wood or cork placed between them, which keep the plates about one-fourth of an inch asunder.

There are many important points of inquiry respecting the phenomena of the voltaic pile, or battery, which cannot be conveniently investigated by any of the preceding arrangements; some of these will be already apparent, and others are connected with effects to which we shall presently advert: to facilitate the experimental examination of such and other questions, Professor Daniell constructed what he termed a *dissected battery*; it is a circular arrangement of ten cells, each provided with a platinum and zinc plate (the latter being amalgamated) and which admit of being combined together in different ways. Over each platinum plate is an inverted and graduated glass tube, filled with the same dilute acid as the cell, in which the hydrogen gas disengaged may be collected and measured.

The following description and figures of this battery are from Mr. DANIELL'S *Introduction to the Study of Chemical Philosophy*, § 726, &c.

"Fig. 156 represents a single cell of this dissected battery. v w x z z y, is a glass cell resting by its wide rim in a circular hole in the stand c d. i j is a zinc plate, connected by a wire passing through the stopper a b c d, with the mercury cup o, on either side of which is a platinum plate, both of which terminate by wires in the mercury cup, p. Either of these may be used singly by removing the other. The different connexions of the plates with the associated cells may easily be made by wires passing between the mercury cups.

"The whole arrangement of the ten cells with the graduated glass jars is exhibited in the next figure. They are placed upon a stand, a b c d e f, and the connexions between them are easily made and varied by the mercury cups, i p k g," &c.

Mr. Daniell observes, that "however accurately it may be endeavoured to assimilate the cells to each other, it will be found that when connected as single circuits, either singly or together, the action of each will differ; but upon connecting them so as to form a single circular series, the inequalities will disappear, and the amount of gas from each in equal times will be equal. When the cells are combined together in pairs, two adjoining platinum plates being connected, and two corresponding zinc plates, and the five pairs are afterwards arranged in series by wires, leading from each pair of zinc to the next pair of platinum, the irregu-

larity of the action will again disappear. The arrangement is equivalent to a series of five plates of double the standard size, and the amount of force which circulates is determined by the least efficient pair.

“Leaving one pair of cells thus connected, if the others be disunited and recombined with it in single series, the effect will be that of a plate of double size, interposed in a compound circuit with eight single. The gas collected in each of the jars of the double cell will be exactly half of that in the several jars of the single cells; proving that the double plate is reduced in efficiency to the exact standard of the single plates by its combination with them.

“In these arrangements every cell is a generating cell, and adds something to the quantity or intensity of the circulating force; and we see that unequal quantities cannot be generated and circulate in different parts of the same circuit. The effects of various retarding or opposing cells may be strikingly exemplified by the same apparatus. For this purpose the cells may be connected together in single series, substituting in one a platinum plate for the zinc; and the obstacle will be found to react upon the whole series; the action will be found to be reduced by more than one-third, and the quantities of gas collected from each generating cell will be exactly equal to that collected from the retarding cell. Upon repeating the experiment with a similar change in the next cell, the quantity of hydrogen in all the jars will be equal, but reduced to little more than one-tenth, and the current will be apparently stopped by three retarding cells to seven generating cells.”

Mr. Daniell also observes, that "when one of the zinc plates is removed from the regular series, and replaced by a platinum plate which has been previously coated with copper by the influence of hydrogen evolved in a circuit, the phenomena are striking and instructive. No gas will at first be evolved from the coppered plate, but it will oxidate, and the progress of the oxidation may be traced by the gradual blackening of its surface. The oxide, again, will be gradually dissolved, and the bright white surface of the platinum will make its appearance, and oxygen gas will begin to rise from it. At that moment the current will receive a check, which will be appreciable in all the air-jars.

"This mode of measuring the amount of current affinity by its chemical effects, has been applied in the construction of instruments, to which the name of Volta-meter has been given. They consist, in fact, of an independent closed cell, with two platinum plates, from which the gas may be conveniently collected and measured with great accuracy. They may be readily included in any circuit, and, although they check the current in all its parts, they accurately measure the amount which passes through them.

"When a Volta-meter is substituted for one of the ten cells, and the nine have a portion of nitric acid added to their charge, the quantity of hydrogen evolved from their conducting plates is greatly diminished, and becomes irregular; but the quantity of hydrogen indicated by the instrument is nearly treble that of the cells with their original charge.

"By observations made in this manner, it will be soon found that the action of such a compound circuit is not constant; and that it will gradually decline by a quantity which will be quite appreciable at intervals of five minutes. By breaking the connexion for a short period, its energy will be partially recovered, but will again decline as the action is renewed. Upon allowing the charge nearly to exhaust itself, it will be seen that the platinum plates have become incrustated with metallic zinc, originating, doubtless, from the oxide of zinc formed at the generating plates, and reduced by adhering hydrogen at the conducting plates. Its varying quantity and accumulation are amply sufficient to account for the variation and ultimate annihilation of the circulating force; for zinc thus becomes opposed to zinc, and the circuit is destroyed. The momentary breaking of the connexion allows the acid to dissolve off the zinc, which being in contact with the platinum is most favourably disposed for this local action, and upon restoring it, the circulation returns to its first amount, but again speedily declines from the same cause."

All the forms of voltaic apparatus above described, as well as others which have been devised, are open to the serious objection of inconstancy of action; many causes, some of which are obvious from the description just given of the "*dissected battery*," co-operate to render their power uncertain, and in all it decreases in consequence of the decreasing chemical energy of the interposed liquid upon the generating plate; so that many researches, in which not only the continuous but the equal action of an electrical current during several hours was required, could not be undertaken. This obstacle to the progress of electro-chemical science has been obviated by the invention of the "*constant battery*," contrived also by Professor Daniell (*Phil. Trans.* 1836, p. 117). He describes it

as follows. (*Introd.* § 737). "A cell of this battery consists of a cylinder of copper $3\frac{1}{2}$ inches in diameter, which experience has proved to afford the most advantageous distance between the generating and conducting surfaces, but which may vary in height according to the power which it is wished to obtain. A membranous tube, formed of the gullet of an ox, is hung in the centre by a collar and circular copper plate resting upon a rim placed near the top of the cylinder; and in this is suspended, by a wooden cross bar, a cylindrical rod of amalgamated zinc half an inch in diameter. The cell is charged with a mixture of 8 parts of water and 1 of oil of vitriol which has been saturated with sulphate of copper; and portions of the solid salt are placed upon the upper copper plate, which is perforated like a colander for the purpose of keeping the solution always in a state of saturation. The internal tube is filled with the same acid mixture without the copper. A tube of porous earthenware may be substituted for the membrane with great convenience, but probably with some little loss of power. A number of such cells admit of being connected together very readily into a compound circuit, and will maintain a per-

fectly equal and steady current for many hours together, with a power far beyond that which can be produced by any other arrangement of a similar quantity of the metals.

"One of the cells of the constant battery is represented in the annexed cut (fig. 158). *abcd* is a copper cylinder, in which is placed a smaller cylinder of porous earthenware. Upon the upper part of the copper cylinder rests a perforated colander, *ik*, through which the earthenware cylinder passes. *lm* is a cast rod of amalgamated zinc, resting upon the top of the interior cylinder by a cross piece of wood, and forming the axis of the arrangement. The cell is charged by pouring into the earthenware cylinder water acidulated with one-eighth part of its bulk of oil of vitriol, the space between the earthenware tube and the

copper being filled with the same acidulated water saturated with sulphate of copper; and solid sulphate of copper being placed in the colander."

A number of such cells may be connected into a compound circuit, by wires attached to the copper cylinders, and fastened to the zinc by clamps and screws, as shown in fig. 159.

In the common battery, charged as it usually is with a mixture of sulphuric and nitric acid diluted with water, much local action takes place upon the zinc plates without contributing to the circulating forces, and whilst it is in action the oxide of zinc is reduced by the copper plate. In Mr. Daniell's battery these effects are avoided; the local action is prevented by the amalgamation of the zinc rod, and, upon the copper, nothing but copper can be precipitated*.

The quantity and intensity of the electricity of the voltaic battery depends, as above stated, upon various causes; *quantity* being increased by *extent of surface*, and by *chemical action*, and *intensity*, by *number of alternations*; the best charge for all ordinary purposes consists of a mixture of about 80 or 100 measures of water, two of sulphuric acid, and one of nitric acid. Mr. Faraday's observations on this subject will be found in Series X. of his *Researches*.

The *electro-polar* state of the voltaic battery, that is, the state of its extremities when unconnected, resembles that of De Luc's column, and although the intensity of its electricity is in general feeble, it may be rendered evident by a delicate gold-leaf electrometer, or by the condenser, or by the form of electrometer represented in fig. 145, in which one of the leaves being connected with one extremity, and the other with the opposite extremity of the battery, will become mutually attractive. These effects of *tension*, as belonging to the voltaic pile, are best observed when the alternations are very numerous, the troughs well insulated, the plates perfectly clean, and charged, not with acid, but with water. This I had a good opportunity of witnessing in a large battery of 2000 double plates, constructed, under the direction of Mr Pepys, for the London Institution. When quite new and clean, it was insulated upon wine-bottles, and charged with river-water; it gave a shock resembling that of a Leyden phial, and required some time to recharge itself; the sparks were feeble, but it was permanently active upon the electrometer, and a pith-ball attached by a thread to its positive pole was attracted, at some distance, by another attached to its negative pole; it also communicated a charge to a Leyden battery, when the wires from its extremities were respectively connected with the inner and outer surfaces of the jars. But with all this

* Among the numerous modifications of the voltaic battery lately suggested, there are several which deserve the attention of the practical chemist, especially those of Mr. Smee (*Phil. Mag.*, April, 1840), and Mr. Grove (*Phil. Mag.*, October, 1839). In Mr. Smee's arrangement, silver, or plated copper covered by a film of galvanically precipitated platinum, is used as the negative element, the general construction and intervening liquid being the same as in Wollaston's battery. In Mr. Grove's battery the generating metal is zinc acted on by dilute sulphuric acid; the other element is platinum in nitric acid. These are arranged as in Daniell's constant battery, the inner cells being of porous earthenware. Plumbago, and some of the dense forms of coke, have also been successfully employed as the negative element of the battery.

manifestation of intensity, the energies depending upon *quantity* were very feeble.

It will be observed, that in respect to De Luc's column as well as to the voltaic battery, where single pairs of plates are frequently repeated, the terms *positive* and *negative*, as applied to the zinc and copper or silver ends, are apparently the *reverse* of those applied to the simple circle. The actual direction of the electric current is the same in both cases, but in the simple circle the conducting wire communicates directly with the plate in contact with the fluid part of the apparatus, while in the compound circle it is connected, not with the plate necessarily immersed, but with that associated with it, and therefore of a different kind. The *compound circle*, reduced to its condition of greatest simplicity, would be represented by the following series, consisting of five parts, namely:

copper—zinc—fluid—copper—zinc.

In this arrangement the copper end is negative, and the zinc end positive. By merely removing the two terminal plates, which in fact are no way concerned in the effect, we bring it to the state of the simple circle, consisting of

zinc—fluid—copper,

in which we find the zinc end negative and the copper positive; this will be evident by inspecting figs. 152 and 153.

The termination of the conductors or wires, connected with the opposite ends of the voltaic battery, are commonly termed its positive and negative *poles*, a term which becomes objectionable when we ascribe to them certain attractive and repulsive powers, and other effects which are the result, not of forces residing in the *poles*, but of the passage or current of electricity; the *poles*, as they are usually termed, are merely the surfaces by which the electricity comes in and goes out; they act simply as a *path* or door to the electric current: in place of the term *pole*, therefore, Mr. Faraday uses *electrode* (from $\eta\lambda\epsilon\kappa\tau\rho\nu$ and $\omicron\delta\omicron\varsigma$ a way), meaning thereby that substance or surface, whether of air, water, or metal, which bounds the extent of the decomposing matter, or electrolyte, in the direction of the electric current. The place at which the electricity enters the electrolyte, he terms the *anode*, that at which it leaves it, *cathode*, in reference,

if we suppose the current of electricity to follow the passage of the sun, (that is, to pass from east to west,) in its rising and setting. If, for instance, we suppose a current of electricity traversing a wire in the direction of the darts

in the annexed diagram, and entering at E, then, on separating the wire at p, p' p' would become its *poles* or *electrodes*; and p' would be the positive, or emitting electrode, or the *anelectrode*; and p'' the negative or receiving electrode, or the *cathelectrode*. E being the wire which (in common language) is connected with the zinc end, and w' that connected with the copper end of the battery. Such, therefore, is the meaning which must be attached to the term *poles*. And, supposing the chain of circles $c A$ to represent the *electrolyte*, A would be its *anode*, and c its *cathode*.

Mr. Daniell uses the terms *zincode* and *platinode* instead of positive pole and negative pole, or anelectrode and cathelectrode.

When a powerful voltaic battery is in good action, the following effects are perceived. On making the communication between its extremities by charcoal points, a vivid light and intense heat are produced; and, on slowly withdrawing the points from each other, a constant current of electricity passes between them, producing an arc of light of such intensity as scarcely to

be borne by the unprotected eye, and of the form represented by figure 161. When the charcoal points are gradually withdrawn from each other in a vessel exhausted of the greater portion of its air, as in the apparatus represented by figure 162, the effect is even more brilliant.

The extreme intensity of the *heat*, in this arc of flame, is rendered evident by exposing in it very difficultly fusible substances, which readily melt: even substances infusible by all ordinary methods are thus liquified.

When gold, silver, zinc, or copper leaf are interposed between the poles, they are ignited and burned; and fine wires are heated red or white-hot, according to their lengths and diameters: with an iron wire the combustion is extremely brilliant. All these effects upon good conductors, depending chiefly upon *quantity* of electricity, are most effectively produced by *large plates*. The most formidable battery hitherto constructed is described by Mr. Children. (*Phil. Trans.*, 1815.) The plates were two feet eight inches wide, and six feet high, the copper being opposed to both surfaces of the zinc: these were properly fastened to a beam of wood, suspended by counterpoises from the ceiling of the laboratory, so as to be readily and safely immersed into, or removed from, the cells of acid, which were twenty-one in number, and their united capacities amounted to 945 gallons. A leaden pipe, three-fourths of an inch diameter, was attached to the extreme plate at either end, and immersed into separate basins of mercury, by means of which perfect metallic contact was ensured. The charge consisted of a mixture of nitric and sulphuric acids, with thirty, or occasionally only twenty, parts of water.

When the poles of this arrangement were united, as shown in figure 163, by a platinum wire eleven-hundredths of an inch diameter, it became red-hot for a length of five feet six inches. In the same way, it ignited eight feet six inches of the same wire of forty-four hundredths of an inch; and a bar of platinum, one-sixth of an inch square,

and two and a quarter long, was not only heated to bright redness, but fused at the end. A number of intractable and very difficultly fusible substances, submitted to the high temperature occasioned by the discharge of this battery through charcoal points, exhibited indications of the most intense heat; but perhaps the most interesting results were obtained by transmitting the electricity through *different* metallic wires. For this purpose either single wires, or two wires of dissimilar metals, were used, of equal diameter and length: one end of each was in contact with one of the basins of mercury communicating with the poles of the battery, and the other end bent to an angle, and the wires connected continuously by hooking them together. The length of each wire was eight inches, and the diameter one-thirtieth of an inch.

Platinum and gold being thus connected, and introduced into the electrical circuit, the platinum was instantly made red-hot, whilst the gold remained unaffected. With a similar arrangement of gold and silver wires, the gold was ignited, the silver not. With gold and copper, both metals were equally heated to redness. With gold and iron, the iron was ignited, the gold not affected. Alternations of platinum and silver three times repeated, all the platinum wires were ignited, but none of the silver.

These experiments, which may be made with a less powerful battery, are extremely beautiful and instructive, especially the last: for this purpose select some fine silver and platinum wire, and cut it into lengths of about two inches; then form a continuous wire by joining these lengths

endways, in alternate order, and suspend it in a festoon between two thick copper wires, forming the poles of the battery, as in fig. 164, having previously tem-

porarily united these poles by a thick copper wire, as is shown at *a* in fig. 163; on removing the latter, the electricity traverses the compound wire, and occasions the ignition of the platinum portions of it only, the silver being unaffected. The object of uniting the poles by a thick copper wire, whilst the compound wire is being attached, is to prevent the sudden fusion of the latter at the point of contact, which often happens when this precaution is not taken.

The cause of these appearances was referred by Mr. Children to the different *conducting powers* of the metals; that platinum conducts electricity less perfectly than silver, and that, consequently, the electric fluid, meeting with greater resistance in its passage through that metal, elicits light and heat; while, on the other hand, passing with comparative facility through the silver, no such effect is there observed. It is obvious that this explanation rests upon the supposition, that resistance to the passage of electricity occasions the development of heat; and as this must be inversely as the conducting power, when any two of the wires, connected continuously, are placed in the circuit, that which is the worst conductor must be most heated; and silver, therefore, which is the best conductor, is not heated red when connected with any other metal.

Mr. Daniell has described (*Phil. Trans.*, 1839, p. 92) the powerful effects of a constant battery of 70 cells. The flame formed a continuous arch of three-fourths of an inch, which striking distance was not increased in vacuo: it was dangerous to the eye, even when protected by coloured glasses, producing, when reflected from an imperfect parabolic mirror in a lantern, inflammation and a scorching like that of the sun: the rays were collected into a focus by a glass lens, and readily burned paper at many feet from their source. The heat was intolerable to the hand when held near the lantern. Paper, steeped in nitrate of silver, was quickly discoloured in the light. The transfer of charcoal from the positive to the negative electrode, produced a cavity in the former and a protuberance upon the latter; and when a platinum rod was substituted for the charcoal forming the negative pole, the transfer from the charcoal at the positive pole still took place, and the metal was coated with carbon, beautifully moulded to its extremity. When this arrangement was reversed, particles of platinum were transferred, and the charcoal on the negative pole became covered with globules of the fused metal. No spark could be made to pass from one electrode to the other, (even when separated by the smallest stratum of air,) previously to the electrodes having been brought into contact; but when two brass balls formed the poles within a very minute distance of each other, and the spark of a small Leyden jar was passed between them, then the battery current was immediately established, and the balls burned*. Mr. Daniell supposes that the Leyden discharge transferred the conducting matter (particles of brass in this case), which was essential to the existence of the voltaic flame, and which was afterwards supplied by its own energy. The arch of flame was attracted and repelled by the poles of a magnet, and it rotated when the flame was drawn from the pole of the magnet itself included in the circuit. The intensity of heat on the side of the positive electrode was much greater than that of the negative. When two stout copper wires of one-fifth of an inch diameter were connected with the extremities of the battery, and held across each other, so that the flame passed between them, the wire at the positive end became red hot, while the other remained comparatively cool. A bar of platinum, one-eighth of an inch square, melted into globules in the former situation, but showed no signs of fusion at the negative electrode. When the positive electrode was formed of the hard carbon taken from a gas retort, and a cavity ground in it, the most infusible metals placed in it were melted in considerable quantities. Rhodium, the native alloy of iridium and osmium, the native ore of platinum, and titanium were thus fused.

The quantity and the intensity of the electricity in the voltaic pile are respectively modified, as has been stated, by the size and number of the plates, and by the action of the intervening liquid. When the zinc plates are perfectly clean, pure water produces certain electrical effects; these are considerably modified by dissolving common salt in it, or employing other saline liquids; but the dilute acids are best calculated

* In reference to the question whether a spark can be obtained before the circuit of the voltaic battery is complete, and also for a description of the brilliant effects of a constant battery of 320 series, see two papers by Mr. Gassiot. *Phil. Trans.*, 1839, p. 183, and *Transactions of the Electrical Society*.

to increase them. If, for instance, we charge three single troughs, each of ten pairs of plates, with water, brine, and very dilute nitric acid, the first will show scarcely any signs of electricity; the second will give a feeble spark and shock; the third will ignite the charcoal points, producing a continuous star of brilliant light. The first will not decompose water; the second does it feebly; the third rapidly. It is obvious, therefore, that with a small number of plates *highly* charged (that is, with dilute acid), we obtain effects equivalent to those of a larger series *feebly* charged; the experimentalist must therefore regulate the strength of the charge according to the number of plates, and the effects which are required. (See FARADAY'S *Researches*, Series X.)

All the effects of *electrical intensity*, such as affecting electrometers, giving shocks, charging jars, decomposing water and saline solutions, and so forth, are, as above remarked, increased by increasing the *number* of the plates, but (*the charge being in both cases the same*) the production of *quantity* of electricity becomes dependent upon the extent of surface of the plates. Thus, if a battery composed of thirty pairs of plates, *two inches square*, be compared with another battery of thirty pairs of *twelve inches square*, scarcely any difference will be perceived in their effects upon *bad* and imperfect conductors; their powers of decomposing water and of giving shocks will be nearly similar; but upon *good* conductors, the effects of the large plates will be very distinct from those of the small ones; the spark, and arc of light between charcoal points, will be much more intense and extensive; and when the charge is transmitted through a fine platinum wire, much of it will be heated red hot; an effect which the small plates are quite inadequate to produce.

The following experiments are adduced by Sir H. Davy, as illustrating these relative effects of *quantity* and *intensity* in the voltaic apparatus:—

Immerse the platinum wires, connected with the extremities of a charged battery composed of *twelve-inch* plates, into water, and it will be found that the evolution of gas is nearly the same as that occasioned by a similar number of *two-inch* plates. Apply the moistened fingers to the wires, and the shock will be the same as if there were no connexion by the water. While the circuit exists through the human body and through the water, let a wire, attached to a thin slip of charcoal, be made to connect the poles of the battery, and the charcoal will become vividly ignited. The water and the animal substance discharge the electricity of a surface probably not superior to their own surface of contact with the metals; the wires and charcoal discharge all the residuary electricity of the plates; and if a similar experiment be made upon plates of an inch square, there will scarcely be any sensation when the hands are made to connect the ends of the battery, a circuit being previously made through water; and no spark when charcoal is made the medium of connexion, imperfect conductors having been previously applied.

In all the preceding arrangements two metals and a fluid are concerned in the evolution of the electric current, and in the case of zinc, acid, and copper, the zinc is termed the generating plate, being that which is oxidized, and the copper the conveying or conducting plate; but, by using certain liquids which act chemically upon the copper and not upon the

zinc, the direction of the current may be inverted, and the copper may become the generator, and the zinc the conductor.

It is, however, by no means essential that two metals should be employed to obtain an electric current; for if only one metal be used, different parts of which are unequally acted on by an acid, or other fluid, electricity will be evolved according to the same law; the portion of the metal most acted on becoming the generator or positive element: thus a current is established when a plate of new and clean zinc and one of oxidized or corroded zinc are used, or when one of the plates is of cast and the other of rolled zinc. Upon the same principle when a strip of copper, clean at one end and corroded at the other, is immersed in dilute nitric acid, an electric current is produced; in all these cases the surface, which is most open to chemical action, corresponds to the zinc, and that least so to the silver or copper of the simple circle above described.

An electric current is also manifested when a single plate of metal of uniform surface is acted upon by two fluids exerting distinct chemical actions upon it. If, for instance, a vessel be half filled with a strong solution of sulphate of copper, and then carefully filled up with dilute sulphuric acid, so that the latter may lie upon but not mix with it, a plate of iron immersed will be so acted on as to produce an electric current, the upper part becoming the equivalent of the zinc, and the lower that of the copper in the simple circle. A plate of copper immersed in the same way will produce a similar effect, and metallic copper in a crystalline form will be deposited upon its lower end. These, and similar phenomena in reference to the source of power in the voltaic pile, have been laboriously investigated by Faraday, in the sixteenth and seventeenth series of his "Experimental Researches in Electricity."—*Phil. Trans.*, 1840.

§ 12.—ELECTROLYSIS.

The *chemical powers*, as they are usually termed, of the voltaic pile were first observed in regard to the decomposition of water and certain saline solutions, by Messrs. Nicholson and Carlisle, in the year 1800, (*Phil. Mag.*, vii., and *Nich. Jour.*, 4to., iv., 183); these were then more accurately investigated in 1803 by Hisinger and Berzelius (*GEHLEN'S Jour.*, i., 115), and, in 1807, Sir H. Davy communicated his celebrated lecture "On some chemical agencies of Electricity" to the Royal Society, in which the electro-chemical powers of the pile were more minutely examined, and which formed the groundwork of the brilliant discoveries to which he was soon afterwards led. There were, however, many important phenomena, more especially those connected with the development of electricity by chemical action, and with the theory of electro-chemical decomposition, which Sir H. Davy, and others, whose researches have enlightened this difficult department of experimental science, either left unexplored, or insufficiently and unsatisfactorily explained: these have lately engaged the attention of Professor Faraday; and his "Experimental Researches in Electricity," published in a succession of papers, communicated to the Royal Society (*Phil. Trans.*, 1832 to 1840), contain the results of his labours, in reference to this branch of knowledge. They have not only, as our preceding pages have shown, explained and enlightened much

that was before unintelligible and obscure in regard to statical electricity, but have also stamped a new character upon electrical as connected with chemical science; in point of originality in devising experiments, skill in carrying them into effect, and perspicuity in tracing out and unravelling the complicated relations and bearings of the new truths which are elicited, he stands, if not unrivalled, at least unsurpassed.

When the electrodes of the voltaic battery are brought near to each other in certain liquids, such, for instance, as *water* and *saline solutions*; or, in other words, when these liquids are made part of the electric circuit, so that the current of electricity passes through them, they are *decomposed*; that is, they yield up their elements in obedience to certain laws; *water*, for instance, is resolved into *oxygen* and *hydrogen*; and the acid and alkaline matter of the neutral salts, which it holds in solution, are separated. In these cases, the elements appear at the poles, or electrodes; not indiscriminately, or indifferently; but the *oxygen* and acids are developed at the *anode*, or surface at which the electricity enters the electrolyte; and the *hydrogen*, and the alkaline bases, at the *cathode*, or surface at which the electric current leaves the body under decomposition.

As the elements of substances thus electrically decomposed are uniformly separated at one or other electrode, it has been assumed that the natural or inherent electricity of such elements is the antagonist of that supposed to belong to the surface at which they appear; in conformity to the law already laid down, "that bodies dissimilarly electrified attract each other;" it has further been assumed, that the elements of compounds are held together by certain electro-chemical forces, more feeble than those belonging to the pile, and that they are consequently overcome by such superior power; that when substances (or their atoms) are similarly electrical they will refuse to combine; and that substances which, in their ordinary states, exhibit no mutual affinities, may be made to enter into combination by communicating to them dissimilar electrical states.

But in classing bodies according to their electrical relations, it is important to state those relations, without involving the expression of hypothetical views, and to this end, Mr. Faraday uses the following terms. All substances susceptible of *direct* decomposition by the electric current, he calls, as already stated, *electrolytes*; *water* therefore is an *electrolyte*; and for the term *electro-chemically decomposed*, he substitutes *electrolysed*. Those elements of the electrolyte which are evolved at the *anode*, he terms *anions*, and those which are evolved at the cathode, *cations*, (*ανιον*, that which goes upwards; *κατιον*, that which goes downwards, in reference to *anode* and *cathode* already defined,) and when these are spoken of together, they are called *ions*: thus, *water* when *electrolysed*, evolves two *ions*, oxygen and hydrogen, the former being an *anion*, the latter a *cation*.

I shall now proceed to a few experimental illustrations of *electrolysis*, or *electro-chemical decomposition*, and afterwards consider the general laws which have been deduced from them*.

* The terms positive and negative pole are used in speaking of electro-chemical action in two senses: they are fre-

quently employed in reference to certain supposed attractive and repulsive powers belonging to them, and with the same

If two platinum electrodes be brought near each other in water slightly acidulated by sulphuric acid, a stream of gas will issue from each, which in an apparatus similar to fig. 165, may be collected, and examined. *a* is a glass globe with three apertures; two of these (on the sides) are fitted with corks perforated by glass tubes of such length as to approach the centre of the globe, and traversed by platinum wires, which are flattened out into plates at the ends, and turned upwards, within a tenth of an inch of each other. The tube *b* is inverted into the neck of the globe, which it fits loosely, so as to admit of the oozing of a portion of water. This apparatus is then filled with the acidulated water, and the hooked ends of the platinum wires made to communicate with the conducting wires of the voltaic apparatus; gas immediately bubbles up into the tube, and the displaced water trickles out at the neck of the globe. It will be observed, that twice the quantity of gas escapes at the negative pole, or the *cathode* of the water, as compared with that at the positive pole, or at the *anode* of the water: and the tube will be found to contain a mixture of *hydrogen* and *oxygen* gases, in the proportion of *two* volumes of the *former* liberated at the *cathelectrode*, or *negative pole*, and *one* of the *latter* at the *anelectrode* or *positive pole*. If a lighted candle be brought to the mouth of the tube, the mixed gases explode and produce water.

By a simple modification of this arrangement, the evolved gases may be collected in separate tubes; as, for instance, if we employ a globe with two orifices (fig. 166), each having a tube so adapted as separately to receive the gas from each pole. It will then be seen that *two* volumes of *hydrogen* gas, and *one* volume of *oxygen* gas, are respectively collected in the tubes inverted over the *negative* and the *positive* poles. Upon the approach of a taper, the hydrogen gas will burn quietly with a blue lambent flame; and

meaning as in speaking of quiescent electricity; but, in reference to electricity in motion, they refer to the surface or passage by which the electricity passes into, and out of the body, under decomposition. In the case, for instance, of a current of electricity traversing a wire or any other substance, and passing from east to west, if we make a break in it, the eastern side of the divided part becomes the positive pole, and the western the negative pole, as may be learned from the diagram fig. 160. But this explanation only applies to the hypothesis of a single electric fluid, traversing the conductor in a given direction: if we assume *two* electric fluids, we must suppose that they traverse the wire con-

necting the poles of the battery in *opposite* directions, in which case, the positive electric fluid must be assumed to issue from the positive pole, and re-enter by the negative; and the negative fluid to issue from the negative pole, and re-enter by the positive. Mr. Daniell calls the positive pole, or the *anelectrode*, the *zincode*; and the negative pole or *cath-electrode*, the *platinode*; the former being the electrode, which in the regular battery would be constructed of zinc, and the latter of platinum. Professor Graham uses the terms *zincous* and *chlorous* poles, the former having the characteristic affinities of zinc, for oxygen, chlorine, &c., the latter those of chlorine, for hydrogen and the metals.

the oxygen may be recognised by immersing into it the glowing wick of a small piece of green taper, which will instantly kindle into flame*.

These experiments are here merely adduced in illustration of the decomposing or electrolytic powers of the current; they show that, under whatever circumstances water is decomposed, the hydrogen is evolved at the cathode, (or at the negative pole,) and the oxygen at the anode, (or positive pole). They are, however, further important, as establishing the composition of water; for, if we reduce the volumes of the gases to their respective *weights*, we shall find that, the volume of hydrogen being = 1, the half volume of oxygen will be = 8, and, consequently, nine parts of water will consist of one part *by weight* of hydrogen, and eight parts *by weight* of oxygen, for the specific gravity of oxygen to hydrogen is as 16 to 1. Hence another verification of the *atomic theory*, in reference to the composition of water and the volumes of its elementary gases (p. 286).

If, instead of pure water, in the experiments just described, we employ *hard* or pump water, we find, that the *saline ingredients*, present in such water, are decomposed, and that their elements are also separated according to certain laws. This may be more strikingly illustrated by dissolving some *salt*, of known composition, in water, and electrising the solution, as in the following experiment. Provide a piece of glass tube, bent at an angle, and placed in a wine-glass, to serve for its foot or support. Fill this syphon with the blue infusion obtained by macerating the leaves of the red cabbage in boiling water, and put into it a few crystals of *sulphate of soda*; then place a strip of platinum foil in each leg of the syphon, taking care that they do not come into contact at the elbow of the tube, and connect one of these with the negative, and the other with the positive, pole of the pile: in a few minutes the blue colour will be changed to *green* in the negative side, and to *red* in the positive side of the tube, indicating

the decomposition of the salt, the alkali or *soda* of which is collected in the *negative*, and the *sulphuric acid* in the *positive*, side. Reverse the poles, and the colours will also gradually be reversed. In this and analogous experiments, it is found that, whenever a neutral salt is decomposed by electricity, the oxide or base is thrown off at the cathode, and the acid at the anode. The bases, therefore, in their electrical relations, rank with hydrogen, and are cathions; and the acids with oxygen, and are anions.

The most insoluble and difficultly decomposable salts may be made to render up their elements in the same way. If, for instance, we substitute for the sulphate of soda in the preceding experiment, a little finely-powdered *sulphate of baryta*, which is insoluble in water, baryta will be

* In these experiments we employ water, to which a small portion of sulphuric acid has been added, and by which its transmitting power in regard to the electric current is much improved; the results are then more rapidly obtained, and by a lower power, but in other respects, not interfered with by the acid.

evolved at the cathode, and there render the liquor green; and sulphuric acid at the anode, rendering it red.

These experiments may be instructively varied as follows:—fill two glasses, connected together by a syphon of large bore, with the blue solution of *sulphate of soda*, and invert in each glass a tube of the same solution, into the upper ends of which platinum wires, terminating in long strips of the same metal, are inserted, as shown in fig. 168; connect these wires with the battery so as to make them the electrodes, and it will presently be remarked that, notwithstanding they are in separate vessels, the blue liquor will, as before, be rendered green and red; and if the experiment be continued for a sufficient length of time, the alkali of the salt will have passed from the side P to N, and the acid from N to P. The acid and alkali appear, in this case, to traverse the connecting syphon in opposite directions; hence the inference that, under the influence of electrical attraction, the usual chemical affinities are suspended.

The decomposition of *sulphate of baryta* may be effected in the same way; for this purpose, provide two insulated discs, or very shallow cups of platinum (fig. 169), one of which is to be put into communication with the negative, and the other with the positive, end of the pile; place upon each of these a few grains of finely-powdered (artificial or precipitated) sulphate of baryta, moistened by a drop or two of water, and connect the discs (which should be within half an inch of each other) by some filaments of wet cotton, *a*. In a few minutes *baryta* will be apparent to test-papers at the negative disc, and *sulphuric acid* at the positive.

In some of his experiments on these electrical transferences, Sir H. Davy employed vessels consisting of the substance to be decomposed. Two small cups of sulphate of lime, for instance, were filled with water, and united with moist cotton: they were rendered negative and positive by placing one pole of the pile in each cup; the negative cup soon was found to contain a solution of lime, and the positive cup free sulphuric acid.

If the bent tube, fig. 167, be filled with a dilute solution of sulphate of copper, acetate of lead, or nitrate of silver, the metals will be deposited upon the cathode, and no hydrogen will escape. In this way, M. Becquerel, by employing low voltaic powers, obtained some beautiful results, and succeeded in imitating many crystallized substances found in nature but not previously produced by art. Such experiments have been further extended and improved, and some new and important chemical results obtained from them, by Dr. Golding Bird, (*Phil. Trans.*, 1838): they also have been applied very ingeniously to taking impressions of medals and copper-plates; forming

what have been termed *Electrotypes*, an application originating, I believe, with Professor Jacobi and Mr. Spencer. For this purpose, the following modification of the voltaic arrangement may be used. The piece of metal to be copied, suppose an engraved copper-plate or a medal, or an indented impression of a medal in lead, tin, or fusible metal, is connected by a copper wire with a rod or plate of zinc, the wire being soldered at one end to the zinc, and at the other to the medal or plate to be copied, and of any convenient length: a glass open at both ends is then provided, (a lamp-glass sometimes answers the purpose,) and one end is closed either by plaster of Paris, or by tying over it a piece of bladder: it is then suspended within a larger vessel, filled with a solution of sulphate of copper, which must be kept saturated during the process, either by adding fresh sulphate of copper, or by putting some crystals of that salt into the saturated solution. The smaller vessel is then filled with dilute

sulphuric acid, (1 of acid to 8 of water,) and suspended within the larger one containing the sulphate of copper, as shown in the annexed diagram; where A represents the acid-holder with its porous diaphragm D; B the vessel of solution of sulphate of copper, C the plate upon which the precipitation of copper is intended to take place, and which is connected by the wire E with the zinc plate Z. The darts show the direction of the electric current generated by Z, and transmitted through the diaphragm to C, where the hydrogen of the decomposed water reduces the copper, and gradually precipitates it in

a tough metallic layer. When the deposited copper upon C has acquired sufficient thickness, which will generally be in twenty-four hours, it may be removed by carefully loosening its edge with a knife, and then pulling it gently off the mould. Several moulds may, if requisite be connected with the zinc plate. Some other applications of this process, and directions for its performance, are given in a paper by Mr. E. Solly, in the *Philos. Mag.* for March, 1840.

In some of Sir H. Davy's early experiments on the decomposition of water in glass vessels, a considerable quantity of acid and alkaline matter was elicited, which was traced to the glass: to avoid this source of error, therefore, he electrized distilled water in two vessels of gold, properly connected, thus employing a material which could not furnish impurities to the water: still, however, alkali and acid made their appearance. This evolution of foreign matters, by the electrization of *apparently* pure water, had been observed by others; and their appearance was, by some, referred to a power, supposed to be possessed by electricity, of *generating* the matters evolved; it was even imagined that water might possibly be a simple or elementary body, capable of forming an acid in union with positive electricity, and an alkali with negative electricity. In reviewing these and other opinions, it occurred to Davy, that the water, although carefully distilled, and apparently pure when examined by common tests, might still contain minute portions of foreign matter, rendered evident by the decomposing power of electricity. He accordingly carefully redistilled the water at a low temperature in silver vessels, and on employing

it, thus redistilled, it was found to afford much less indication of impurity; but, even after all precautions, acid and alkali were sparingly evolved. Of this impurity, part was traced to the accidental contact of the hands with the apparatus used, the perspirable matter leaving traces of common salt; and now, aware of this source of contamination, and carefully avoiding it, there were scarcely any traces of acid or alkali to be observed. These extraneous elements, however, notwithstanding all the precautions, were still perceptible after the process of electrical decomposition had been carried on for a length of time; and the only probable source whence they could be derived was the atmosphere, the elements of which, by uniting chemically with those of water, might give rise to the formation of nitric acid and ammonia. This chemical action or combination, Davy thought, might possibly be brought about by electric agency; accordingly, in addition to all the previous precautions, he now conducted the experiments in the exhausted receiver of a good air-pump, and found that, under the careful exclusion of all foreign agents, water was resolved into oxygen and hydrogen only; and, consequently, that there were no grounds for supposing that any new forms of matter were producible by the union of electricity with other bodies.

Another important inference was deduced from the above, and similar experiments; it was obvious that electricity overcame the most powerful chemical attractions; might it not, therefore, when properly applied to different bodies, indicate the existence of substances hitherto unsuspected, and even lead to the knowledge of new elements? Proceeding upon such grounds, Sir H. Davy submitted the fixed alkalis, which were considered at that time as elementary bodies, to the decomposing agency of the pile, and was fortunate enough in this, his first trial, to obtain from them new elements: at the positive pole oxygen was evolved, but brilliant metallic globules appeared at the negative pole, extremely inflammable, and which were shown to be the bases of those bodies. The names *potassium* and *sodium* were given to these new and singular metals; and by analogically applying these phenomena of the decomposition of the alkalis to that of the *earths*, also then on the list of elements, they likewise afforded evidence of decomposition, and, like the alkalis, were shown to be combinations of peculiar metals with oxygen. Many other discoveries have been the result of this new mode of research; but these, as well as the above, will be more fully dwelt upon afterwards.

In all *primary* electro-chemical decompositions, the elements of compounds are evolved with uniform phenomena either at the anode or cathode of the electrolyte, and hence were usually, but incorrectly, stated to be *attracted* to one or other *pole*, and upon the supposition of such attractions, and in reference to that law of electrical action which teaches that bodies *dissimilarly* electrified attract each other, it was assumed that the elements evolved at the anode (or apparently attracted by the positive pole) were inherently *negative*, and those evolved at the cathode (or attracted by the negative pole) inherently *positive*; hence their division into *electro-negative* and *electro-positive* bodies, or, in Faraday's terms, into *anions* and *cations*. In the present state of our chemical knowledge, the *elementary* or *simple bodies* may be regarded as about fifty-five in number: of these, five are usually termed *supporters of com-*

bustion, nine are *non-metallic combustibles*, and the remaining forty-two are *metals*. The five former bodies, when evolved from their combinations by electrolytic action, make their appearance at the anelectrode (zincode, or positive pole); the others are usually observed at the cathelectrode (platinode or negative pole), as are also the metals. But it frequently happens that the evolution of a substance at the electrode is a secondary effect; *sulphur*, for instance, in the decomposition of sulphuric acid, is evolved at the negative pole, not by *direct* electrolysis, but in consequence of the action of the nascent hydrogen; and whenever sulphur is obtained by primary electrolytic action from a compound containing it, it is evolved at the anode, or positive pole; hence, in classifying the elements according to their electrical relations, this distinction must be observed. It is also necessary to guard against the combination of the substance evolved (or *ion*), with the electrode; hence the advantage of platinum electrodes, that metal being acted upon by few of them.

The following table of *simple and compound ions* has been drawn up by Mr. Faraday:—

ANIONS.

Oxygen	Cyanogen	Phosphoric acid	Citric acid
Chlorine	Sulphuric acid	Carbonic acid	Oxalic acid
Iodine	Selenic acid	Boracic acid	Sulphur
Bromine	Nitric acid	Acetic acid	Selenium
Fluorine	Chloric acid	Tartaric acid	Sulphocyanogen.

CATIONS.

Hydrogen	Tin	Mercury	Strontia
Potassium	Lead	Silver	Lime
Sodium	Iron	Platinum	Magnesia
Lithium	Copper	Gold	Alumina
Barium	Cadmium	—	Protoxides generally
Strontium	Cerium	Ammonia	Quinia
Calcium	Cobalt	Potassa	Cinchonia
Magnesium	Nickel	Soda	Morphia
Manganese	Antimony	Lithia	Vegeto-alkalis generally
Zinc	Bismuth	Baryta	

Analogy leads us to presume that all simple bodies are *ions*; but this has not yet been experimentally proved in regard to carbon, phosphorus, nitrogen, silicon, boron, and aluminum: several compound bodies, and amongst them alumina and silica, are in the same uncertainty.

The decomposition of water shows the separation of oxygen upon the anelectrode (or positive pole); that of the other, *anions* (or electro-negatives), may be exhibited as follows; and for these, and many other of the experiments of decomposition, the annexed form of apparatus, fig. 171,

171

will be found useful. It is a cell of plate-glass, made by cementing five pieces together with transparent varnish, and supporting them upon a wooden foot, into which they are fastened. The cell is about five or six inches

long, and about an inch broad, and may be divided into two parts, by the insertion of the temporary diaphragm *a*, which is a small frame of cane

with muslin stretched over it. When this is in its place, a separate electrode may be introduced on each side of it: they may most conveniently consist of two pieces of thin platinum, about four inches long and half an inch broad.

To show the evolution of *chlorine* at the anode (or positive pole), fill the glass cell with weak salt and water, acidulated by hydrochloric acid, and coloured blue by the addition of a few drops of a sulphuric solution of indigo; then introduce the electrodes, and in a few minutes the *positive* or *anodic* division will begin to lose colour, and at length become colourless, in consequence of the evolution of chlorine derived from the acid and salt: here, the presence of *chlorine* is rendered evident by its *bleaching power*, which destroys the blue of the indigo.

The presence of uncombined *iodine* is announced by its property of striking a deep blue colour with a solution of starch. To demonstrate its electro-polarity, therefore, fill the cell with a very weak solution of *starch* to which a little common salt and iodide of potassium have been added; then electrize as before, and the *iodine* will show itself at the *anode* (or positive side) by a beautiful *blue* colour.

The presence of *bromine* is announced in the same way by its yellow colour; and of *fluorine* by its action on glass.

The electro-positive bodies, or *cations*, on the other hand, are evolved from their combinations with the anions, at the *cathode* (or negative pole) as is seen in the case of the decomposition of water, &c. There are many striking experiments showing the evolution of the metals at the cathode; and, indeed, whenever solutions of metallic salts are electrolysed, their precipitation at the negative electrode is more or less perfectly observed, according to their facilities of reduction, or deoxidizement*. A plate of silver, for instance, when immersed into a dilute solution of sulphate of copper, occasions no change; but if the silver be made the cathode, (negative electrode,) a precipitation of metallic copper immediately ensues. In the same way solutions of lead, tin, &c., may be decomposed by metals which, under common circumstances, do not effect their decomposition.

When, as in the preceding case, the metals are the cathode, they are at the same time rendered virtually attractive of each other, and of the cations or electro-positive bodies in general: thus, under such circumstances, alkalis, earths, and oxides will be separated upon them; but the same cause which thus renders them apparently attractive of these bodies, renders them as it were repulsive of the anions or electro-negatives, among which are the bodies chiefly characterized by their corrosive and solvent action upon them. A piece of iron, for instance, forming the cathode (rendered *electro-negative*,) will remain bright and clean in water, which, under ordinary circumstances of immersion, would rust and corrode it; but if the iron form the anode (be rendered *electro-positive*,) it then corrodes more rapidly than in plain water; that is, it is

* In the illustrations given in the text, it is to the *results*, that I wish to direct the reader's attention: their *cause*, as I have observed, is frequently a *secondary*, and not a true or *primary*, electrolytic action. There are also many important theoretical considerations arising out of the electrolysis of secondary compounds, more especially affecting our views of the atomic constitution of neutral salts, which will afterwards be noticed. DANIELL, *Phil. Trans.* 1834, p. 97, and 1840, p. 209.

then rendered as it were *attractive* of oxygen, acids, and the other solvent agents, of which, in the opposite case, it is virtually repulsive.

These facts led Davy to infer that certain metallic substances which, under ordinary circumstances, are not acted upon by water and acids, might be rendered *active* by communicating to them the *positively* electrical state; and, on the contrary, that such metals as are easily acted upon by the above-mentioned agents, might be rendered *inert* in regard to them, by giving them the *negatively* electrical state. Silver, for instance, is a metal not acted upon by pure water, nor by salt and water, nor by dilute hydrochloric acid. But, if the electrodes consist of two strips of silver, immersed in water, while the cathelectrode (or negative pole) remains bright, the anelectrode (or positive) becomes discoloured, and a cloud collects about it in the water, which is *oxide of silver*; here, the silver is rendered *attractive* of the oxygen of the water, and combines with it.

If, for water, we substitute a weak solution of common salt, or dilute hydrochloric acid, the *negative* silver will still remain bright, but the *positive* becomes incrustated with a white or gray powder, and is soon corroded; this arises from its being rendered *attractive* of the chlorine contained in the salt and in the acid, and *chloride of silver* is formed.

If we substitute for silver any more oxidizable metal, the effects are still more striking, and we then have a better opportunity of observing the non-action at the negative surface, as opposed to the activity of the positive. For instance, for the silver electrodes substitute two polished plates of *iron*, and immerse them into weak sulphuric or hydrochloric acid, or into a solution of salt—liquids which, under ordinary circumstances, act upon and corrode iron; the negative plate, or cathelectrode, will now remain bright, but the positive, or anelectrode, will be rapidly oxidized and dissolved.

This experiment may be varied and rendered more striking, as follows:—Fill the glass cell, fig. 171, with a weak solution of common salt in distilled water, to which a few drops of a solution of ferrocyanuret of potassium have been added, and immerse one of the iron plates in each partition; the negative side will remain unchanged, but the production of a deep blue colour on the opposite side, will presently announce to the eye the action upon the iron there going on. If we substitute a little infusion or tincture of galls for the ferrocyanuret, the solubility of the iron is then shown by a black tint.

The want of action of the cathelectrode (or negative conductor) shown in these experiments, may be more explicitly illustrated by the following: Silver and copper are readily acted upon by *dilute nitric acid*; it dissolves them with effervescence; but if plunged into the acid when rendered *electro-negative*, (or forming the cathelectrode,) they *resist* its solvent or oxidizing power. It will be borne in mind that, in all these cases of the apparent protection of oxidizable metals in fluids containing water, *hydrogen* is evolved upon the protected surface, whence it either passes off as a gaseous film, or is ready to produce secondary effects by entering into new combinations.

Such cases of the prevention of chemical action may be further illustrated as follows: Dilute some nitric acid with five or six parts of water, so that it may act very moderately upon a piece of *sheet-copper* immersed

into it; in the course of a few minutes the acid will have acquired a slight blue colour from the dissolved copper, which may be rendered more striking by dropping a little of it into a solution of *ammonia*, when a deep blue will immediately announce the presence of copper; but if the copper-plate *be united with one of zinc*, and then plunged into the same acid, it will be found not to have been acted on, the zinc only being dissolved.

Again: immerse a polished plate of iron into a glass of water impregnated with carbonic acid, and in a few hours the water will be discoloured, and a portion of the iron dissolved, as may be shown by the black colour produced on adding infusion of galls. Now, tie a strip of zinc in close contact with the iron, and immerse the two metals into the water: after the lapse of some days, none of the iron will have been taken up; indeed, it will remain as bright as when first put in.

Sir H. Davy aimed at a very important practical application of these facts, as a means of preventing the corrosion of the copper-sheathing of ships. It was generally believed that sea-water had but little action upon pure and well-rolled copper, and that its occasional rapid corrosion depended upon some impurity of the metal, or imperfection in its manufacture. It was found, however, on immersing pieces of the best and purest copper in sea-water, that it soon became covered with a green powder, and was ultimately oxidized and corroded. Davy referred this action to the mutual attraction of the *positive* copper and the *negative* oxygen or acid contained in the water, and, therefore, endeavoured to prevent it by communicating a *negative energy to the copper*, by attaching to it a more oxidable metal, such as zinc, iron, or tin.

In experiments upon the small scale, it was found that a piece of *unprotected* copper, immersed in sea-water, was soon covered by a green powder, part of which was dissolved, and part precipitated; but on attaching to it a piece of zinc, and keeping the metal, thus *protected*, under sea-water, it remained bright and untarnished for several weeks: of the facility, therefore, of thus effectually protecting the copper, there could be no doubt: but a point of great importance in reference to the present question was to determine the relative proportion which it was necessary for the *protecting* metal to bear to the *protected**. When the former was zinc or iron, and amounted to from one-fortieth to one-hundred-and-fiftieth of the copper surface, the latter metal underwent no change or decay; when the zinc was reduced to one two-hundredth, and one four-hundredth, there was some perceptible loss; but it is, to a considerable extent, effectual, where it only amounts to one one-thousandth.

As far, therefore, as *protection* was concerned, the above experiments were satisfactory, and seemed to hold out well-founded hopes of being applicable upon the large scale; but when a negative electric power is thus conferred upon the copper, so as to protect it from oxidizing and corroding agencies, it becomes, (as above explained,) attractive of the cations or electro-positive bodies; among these are the *earthy substances* contained in sea-water, such as lime, magnesia, and some of their compounds: these, therefore, when the plan was adopted upon a large scale,

* See also, in reference to this subject, the curious inquiries of Professor Daniell respecting the mutual relations of the generating and conducting surfaces in voltaic arrangements.—(*Phil. Trans.* 1838, p. 31.)

and a protected vessel sent to sea, were precipitated or deposited upon the copper. Now it seemed, at first, as if this earthy coating would merely act as an additional preservative of the copper; but, unfortunately, the adventitious crust or surface, thus formed, is most favourable to the adhesion of weeds, and of certain marine animals; and these accordingly attached themselves to it so rapidly, and in such abundance, as to render the bottom extremely foul, and to interfere with, and impede the sailing of the vessel. Theory would lead us to expect, that the zinc or iron might be so exactly proportioned to the surface of the copper, as effectually to protect it, without at the same time communicating to it that tendency to attract an earthy crust, which has just been mentioned; but in practice this has been found scarcely attainable*.

It will be obvious, from the preceding details, that electrolytic action tends to the separation both of proximate and ultimate elements; of the separation of the *proximate* elements of compounds, the decomposition of neutral salts furnishes ample instances, in which a compound acid and a compound base are respectively separated at the anode and cathode: whether the sub and super salts or *disalts* and *bisalts* are, or are not, decomposed with precisely the same results, has not, perhaps, been accurately determined, but apparently they are: the case, however, is different with respect to binary compounds of the elementary substances; for among them, (with very few exceptions,) the *proto*compounds, or those consisting of *one atom* or equivalent of an anion, with *one* of a cation, are those only which are directly electrolytic, whilst other binary compounds of the same elements are not so; thus the fused *protochloride*, and *protiodide* of tin are decomposed, but the *perchloride*, and *periodide* are not; these important differences may depend upon conducting power, for no compound which is not, to a greater or less extent, a *conductor*, is susceptible of this decomposition (with the single apparent exception of periodide of mercury, which Mr. Faraday found to insulate whilst solid, but to conduct whilst liquid, and yet was not decomposed).

The cases of *apparent* decomposition opposed to the law just stated are numerous, but they may be referred to *secondary* electrolytic action. When sulphuric acid, for instance, (which is a compound of *one atom* of sulphur, and *three* of oxygen,) is subjected to the action of the electric current, sulphur and hydrogen appear at the cathode, and oxygen at the anode; but as already stated, Faraday has shown that the sulphur is here the result of the action of the *nascent* hydrogen upon the acid, and that in all cases of the true electrolytic decomposition of the sulphurets, the sulphur

* It is to be regretted that the successful applications of scientific reasoning and philosophical discovery to practical purposes, and to the arts of life, are rarely made by their original inventors; and the case before us threatens to turn out an instance of this remark, for a patent has been taken out for covering ships with *iron* plate, protected by zinc; the iron is said to be thus rendered comparatively durable and permanent, and not to have that tendency to become foul, by a little over-protection, which belongs

to copper; whilst its extreme cheapness, in comparison with copper, adds greatly to the value of its application. The galvanic protection of iron by zinc in other cases merits much more attention than it has received; when iron is coated by zinc it is unsusceptible of rust, and in a variety of cases zinc iron is most importantly applicable; but although a "company" was advertised some years ago for the purpose of carrying out this "patented?" discovery, it has never yet been brought into use.

is evolved at the anode, and hence is properly placed in the above table of ions, amongst the anions. He observes, in reference to these cases, that the final result of the action of the electric current upon substances placed between the electrodes, instead of being simple, may be very complicated: that substances may be decomposed either by the direct action of the electric current, or by the action of bodies which that current evolves. There are also two modes by which, in these cases, new compounds may be formed; that is, by the combination of the evolved substances in their nascent states with the matter of the electrode, (of which the formation of oxide of silver, &c., above referred to, is an instance,) or, by their combination with substances, which being contained in or associated with the electrolyte, are necessarily present at the anode and cathode*. This complexity is further increased by the circumstance that such actions may occur simultaneously, and in variable proportions to each other. When the electrolyte is an aqueous solution, or when it contains water, such secondary results are very frequent, but they are not confined to cases where water is present: Becquerel has shown that they are in many instances applicable to the formation of new compounds, and to the imitation of those which are produced by natural operations. (*Ann. de Chim. et Phys.* xxxv. 113.)

Previous to Faraday's researches, it was assumed that all compounds were susceptible of electro-chemical decomposition, and more especially those in which the elements were held together by feeble affinities†; but it is now apparent that conducting power is one essential requisite; and another (probably, at least) a certain atomic relation of the elements to one another; hence a most important application of electrolytic action to the determination of atomic weights. Mr. Faraday has thus expressed this law: "There is but one *electrolyte* composed of the same two elementary ions; hence, only single electro-chemical equivalents of elementary ions, and not multiples, can go to the electrodes." We may infer, therefore, that in the electrolysis of a compound formed of two elementary substances, the elements will be evolved in *single atomic proportions*; hence the inference, that *water* is to be considered as a *primary* atomic combination of single atoms of hydrogen and oxygen: and hence the application of electrolytic action to the determination of the equivalent number of the elements in doubtful cases.

The metallic poles of the voltaic apparatus, or the electrodes, have been spoken of as exerting an attractive power over the elements of the

* The decomposition of a solution of *ammonia*, in which the nascent oxygen of the decomposed water unites to the hydrogen of the ammonia, and sets *nitrogen* at liberty at the anode; and that of *nitric acid*, in which the nascent hydrogen of its water, reacting upon the acid, produces *nitrous acid* at the cathode, are instances of such *secondary* results.

† It follows from Faraday's theory, that the more directly bodies are opposed in chemical affinity, the more easily they are separated by electrolytic action,

provided other circumstances, such as insolubility, deficient conducting power, proportions, &c., do not interfere, "so that in applying the voltaic battery for the purpose of decomposing bodies, not yet resolved into forms of matter simpler than their own, it must be remembered, that success may depend not upon the weakness, or failure upon the strength of the affinity by which the elements sought for are held together, but contrariwise."

electrolyte, but this is not the case, and the common expression, "that certain substances are *attracted* by the negative pole, and others by the positive pole," is so far incorrect, for no *single* elementary substance, or *ion*, has any tendency to pass to either of them; sulphur, for instance, charcoal, or finely-divided metals diffused through water, are indifferent to the transfer or passage of the electricity. The *poles* or *electrodes* may even be *water* or *air*. Thus, if pure water be carefully poured upon a solution of sulphate of magnesia, the platinum conductors may be so introduced and arranged, as to make the saline solution, the anelectrode (positive), and the water, the cathelectrode (negative); in this case magnesia will be deposited *at the line of contact between the water and the solution*, but none of it will pass across the water to the platinum cathelectrode; and in all cases, in which substances have been supposed to travel by mere attraction, a line of compound particles has extended from pole to pole.

It seems proved by Mr. Faraday's experiments, that electricity of very feeble tension may sometimes pass through an electrolyte without effecting its decomposition, and that, in such cases, the decomposition ensues when the conducting power of the electrolyte is improved, or the intensity of the electricity increased. If, for instance, a solution of sulphate of soda be made part of a circuit transmitting electricity of very low intensity, the galvanometer in such a circuit will be deflected, so as to demonstrate the passage of electricity, but no appreciable decomposition of the salt will ensue; on increasing the *intensity* of the current, the deflection of the magnetic needle is not increased, but the acid and alkali of the salt are separated.

Electrolytes differ in the facility with which they yield up their elements to the influence of the electric current, or in the resistance which they offer to electro-chemical decomposition. (Faraday, *Phil. Trans.*, 1834, p. 448.) The following bodies are electrolytic in the order in which they are placed, those which are first, being decomposed by the current of lowest intensity:—

- Iodide of potassium (solution)
- Chloride of silver (fused)
- Protochloride of tin (fused)
- Chloride of lead (fused)
- Iodide of lead (fused)
- Hydrochloric acid (solution)
- Water acidulated by sulphuric acid.

That the chemical power is in direct proportion to the absolute quantity of electricity which passes, was an inference drawn by Mr. Faraday at an early period of his researches, (*Phil. Trans.*, 1833, p. 53,) and afterwards ably demonstrated by a series of conclusive experiments, (*Phil. Trans.*, 1834, p. 102,) which have led to the development of the *definite nature of electro-chemical decomposition*.

Analysis teaches that *water* is composed of 1 part by weight of hydrogen, and 8 of oxygen, and that *oxide of zinc* consists of 32 of zinc, and 8 of oxygen; now suppose a quantity of electricity set free, or in motion, by the oxidizement of 32 parts of zinc by 9 of water, that quantity will also decompose 9 of water by the platinum electrodes,

evolving from it 8 of oxygen and 1 of hydrogen; and the same quantity of electricity transmitted successively through fused chloride of silver, and iodide of lead, so as to decompose them, will evolve 36 of chlorine, and 126 of iodine, at the anodes, and 108 of silver and 104 of lead at the cathodes; these numbers are the exact *chemical equivalents* of the respective elements; accordingly, if we place a portion of *water* anywhere in the electric circuit, the quantity of it which is decomposed, or the quantity of oxygen and hydrogen either separate or mixed, which is evolved, furnishes a *measure*, or mode of expressing the quantity of electricity which has passed in a given interval. Mr. Faraday has constructed several instruments for this purpose, which he terms *Volta-electrometers* or *Voltameters*: among them the two following will be found most useful. *a* (fig. 172) is a straight tube closed at the upper extremity and graduated; through the sides pass the platinum wires *b b'*, being fused into the glass, and connected with two plates within; the tube is fitted by grinding, into one mouth of a double-necked bottle, one-half or two-thirds full of water (acidulated by sulphuric acid to improve its conducting power). The tube is filled by inclining the bottle, and when an electric current is passed through it, the gases evolved collect in the upper part of the tube, and displace the dilute acid, the stopper *c* being left open: when the graduated part of the tube *a* is filled with the mixed gases, the electric circuit may be broken by removing the wires connected with *b b'*, the stopper *c* replaced, and the meter-tube refilled by properly inclining the instrument: a second measure of the gases is then collected, on re-establishing the circuit, and so on.

Another form of the *voltmeter* is the following (fig. 173). It is fixed on a weighted foot *a*, and has the form of a small retort, containing the two electrodes: the neck *b* is narrow and long enough to deliver gas issuing from it into a graduated jar placed in a small pneumatic trough. The electrode chamber, sealed hermetically at the part inserted into the stand, is 5 inches in length, and 0.6 of an inch in diameter; the neck about nine inches in length, and 0.4 of an inch diameter internally.

The chamber *c* is filled up to the neck with dilute sulphuric acid (sp. gr. 1.3). In both these instruments, the contact of the electrodes with each other within the chamber or tube, is prevented by the interposition of pieces of glass-tube.

I must here refer to Mr. Faraday's paper (*Phil. Trans.*, 1834, p. 87, *et seq.*) for some curious and important remarks respecting the influence of different forms of the platinum electrodes in these instruments, and for the experimental proofs, that *variation in the size of the electrodes, causes no variation in the chemical action of a given quantity of electricity upon water*: that their action is uninfluenced by changes in the *intensity*, provided the *quantity of electricity remain the same*: that the quantity

of water decomposed is uninfluenced by the *strength* of the dilute sulphuric acid in the volta-electrometer; that, when other solutions are substituted for the acid, the *constancy of the electrolytic action upon water* is not altered; and that, as before stated, when water, and other electrolytes, are subjected to the influence of the electric current, *the quantity decomposed is exactly proportionate to the quantity of electricity which has passed*, notwithstanding all variations in the conditions and circumstances under which they may at the time be placed.

I shall conclude this part of the subject by the following summary of certain points already adverted to respecting *electrolytes, ions, and electro-chemical equivalents*, taken from Mr. Faraday's seventh series of Experimental Researches in Electricity. (*Phil. Trans.* 1834, p. 111.)

i. A single *ion*, i. e. one not in combination with another, will have no tendency to pass to either of the electrodes, and will be perfectly indifferent to the passing current, unless it be itself a compound of more elementary *ions*, and so subject to actual decomposition. ii. If one *ion* be combined in right proportions with another strongly opposed to it in its ordinary chemical relations, i. e. if an *anion* be combined with a *cation*, then both will travel, the one to the *anode*, the other to the *cathode*, of the decomposing body. iii. If, therefore, an *ion* pass towards one of the electrodes, another *ion* must also be passing simultaneously to the other electrode, although, from secondary action, it may not make its appearance. iv. A body decomposable directly by the electric current, i. e. an *electrolyte*, must consist of two *ions*, and must also render them up during the act of decomposition. v. There is but one *electrolyte* composed of the same two elementary *ions*; at least such appears to be the fact, dependent upon a law, that *only single electro-chemical equivalents of elementary ions can go to the electrodes, and not multiples*. vi. A body not decomposable when alone, as boracic acid, is not directly decomposable by the electric current when in combination. It may act as an *ion*, going wholly to the *anode* or *cathode*, but does not yield up its elements, except occasionally by a secondary action. Perhaps it is superfluous to point out that this proposition has *no relation* to such cases as that of water, which, by the presence of other bodies, is rendered a better conductor of electricity, and *therefore* is more freely decomposed. vii. The nature of the substance of which the electrode is formed, provided it be a conductor, causes no difference in the electro-decomposition, either in kind or degree; but it seriously influences, by secondary action, the state in which the *ions* finally appear. Advantage may be taken of this principle in combining and collecting such *ions* as, if evolved in their free state, would be unmanageable*. viii. A substance which, being used as the electrode, can combine altogether with the *ion* evolved against it, is also an *ion*, and combines in such cases, in the quantity represented by its *electro-chemical*

* It will often happen that the electrodes used may be of such a nature as, with the fluid in which they are immersed, to produce an electric current, either according with or opposing that of the voltaic arrangement used, and in this way, or by direct chemical action, may

sadly disturb the results. Still, in the midst of all these confusing effects, the electric current, which actually passes in any direction through the decomposing body, will produce its own definite electrolytic action.

equivalent. All the experiments agree with this view; and it seems, at present, to result as a necessary consequence. Whether, in the secondary actions that take place, where the *ion* acts, not upon the matter of the electrode, but on that which is around it in the liquid, the same consequence follows, will require more extended investigation to determine.

ix. Compound *ions* are not necessarily composed of electro-chemical equivalents of simple *ions*. For instance, sulphuric acid, boracic acid, phosphoric acid, are *ions*, but not *electrolytes*, i. e. not composed of electro-chemical equivalents of simple *ions*.

x. Electro-chemical equivalents are always consistent; i. e. the same number which represents the equivalent of a substance A when it is separating from a substance B, will also represent A when separating from a third substance C. Thus, 8 is the electro-chemical equivalent of oxygen, whether separating from hydrogen, or tin, or lead; and 104 is the electro-chemical equivalent of lead, whether separating from oxygen, or chlorine, or iodine.

xi. Electro-chemical equivalents coincide, and are the same, with ordinary chemical equivalents.

§ 13.—SOURCE OF VOLTAIC ELECTRICITY, AND THEORY OF THE PILE.

THE electrical equilibrium is so easily disturbed, or, in other words, there are so many causes of electrical excitation, and tending to the production of electrical currents, that it becomes difficult to separate them and to refer to each its due effects: Volta attributed the electricity of the pile to the mere *contact* of the different metals, and regarded the interposed solutions as imperfect conductors, admitting the transfer of electricity when the circuit was completed; and when incomplete, throwing the whole, by induction, into an electro-polar state. This explanation was adopted with some modifications by Sir H. Davy (*Phil. Trans.*, 1807), who seems to have considered the electric state of the pile partly as the consequence of the contact of the opposed metals, and partly of the chemical action of the liquid in the cells; and he concluded, from experiments upon the contact of acids with alkalis and metals, that they became negative and positive in respect to each other*; summing up the whole in the statement, that “Chemical and electrical attractions are produced by the same cause, acting in one case on *particles*, in the other on *masses* of matter, and that the same property, under different modifications, is the cause of all the phenomena exhibited by different voltaic combinations.”—(*Phil. Trans.*, 1826, p. 389.)

Others have referred the electricity of the pile exclusively to chemical action: and Dr. Wollaston not only adopted this opinion (*Phil. Trans.*, 1801), but attributed the activity of the common electrical machine to the oxidizement of the amalgam: this view was opposed by Davy, who, contrary to Dr. Wollaston's experiments, found the electric machine active

* When two metals, or other substances, are brought into contact, and especially when filings of one metal are sifted upon the surface of another, exceedingly feeble *electricity of tension* may be shown by a very delicate electrometer;

but in these cases, and also when solid *acids* and *alkalis* are used, *friction*, change of temperature, and even chemical action, cannot, as already observed, always be avoided.

in atmospheres of hydrogen and of carbonic acid, and in the latter more so than in atmospheric air, probably on account of its greater density.

The phenomena of De Luc's column were considered by some as ample proof of the correctness of the "theory of contact," while others ascribed its electricity to the chemical action of the moisture hygrometrically retained by the paper; but this instrument seems to require more minute and accurate examination before any satisfactory conclusions can be drawn from it*.

That electricity is produced in voltaic arrangements, *independent of contact*, and apparently by *chemical action only*, has been satisfactorily shown by Faraday, for he found that a single pair of plates, so arranged as to avoid metallic contact and every other source of electricity except chemical action, produced a current which not only deflected a galvanometer, but decomposed iodide of potassium. The following was the form of his experiment.—(*Phil. Trans.*, 1834, p. 426.)

A plate of zinc, about eight inches long and half an inch wide, *a* (fig. 174), was cleaned and bent in the middle to a right angle. A plate of platinum, about three inches long and half an inch wide, *b*, was fastened to a platinum wire, and the latter bent as in the figure. These two pieces of metal were arranged together as delineated, but as yet without the vessel *c*, and its contents, which consisted of dilute sulphuric acid mingled with a little nitric acid. At *x* a piece of folded bibulous paper, moistened in a solution of iodide of potassium, was placed on the zinc, and was pressed upon by the end of the platinum wire. When under these circumstances the plates were dipped into the acid of the vessel *c*, there was an immediate effect at *x*, the iodide being decomposed, and iodine appearing at the *anode*, i. e. against the end of the platinum wire. As long as the lower ends of the plates remained in the acid, the electric current continued, and the decomposition proceeded at *x*. On removing the end of the wire from place to place on the paper, the effect was evidently very powerful; and on placing a piece of turmeric paper between the white paper and zinc, both papers being moistened with the solution of iodide of potassium, alkali was evolved at the *cathode* against the zinc, in proportion to the evolution of iodine at the *anode*. Hence the decomposition was perfectly polar, and decidedly dependent upon a current of electricity passing from the zinc through the acid to the platinum in the vessel *c*, and back from the platinum through the iodic solution to the zinc at the paper *x*. That the decomposition at *x* was a true electrolytic action, due to a current determined by the state of things in the vessel *c*, and not dependent upon any mere direct chemical action of the zinc and platinum on the iodide, or even upon any *current* which the solution of iodide might by its action on those metals tend to form at *x*, was shown,

* All the inquiries relating to the source of power in the voltaic pile have lately been submitted to a searching and masterly investigation by Faraday, the details of which (in addition to his former experiments) are contained in the

16th and 17th series of his *Experimental Researches*, already quoted. These papers only reached me whilst the present pages were going through the press, or I should have quoted them more in detail.

in the first place, by removing the vessel *c* and its acid from the plates, when all decomposition at *x* ceased, and in the next by connecting the metals, either in or out of the acid, together, when decomposition of the iodide at *x* occurred, but in a *reverse order*; for now alkali appeared against the end of the platinum wire, and the iodine passed to the zinc, the current being the contrary of what it was in the former instance, and produced directly by the difference of action of the solution in the paper on the two metals. The iodine of course combined with the zinc.

So far, therefore, the evidence of the current of electricity *independent of metallic contact* is complete. It is now to be shown how *chemical action* becomes the source of the electricity in the voltaic battery, and for this purpose it will be necessary to trace it from the simple to the compound circle.

In the following illustrations, for which I am indebted to Mr. Faraday, it is supposed that *pure* zinc is used; which, unlike the common zinc* of commerce, is very slowly acted upon by sulphuric acid diluted with six or eight parts of water.

Let *z* (fig. 175) represent a piece of such zinc, and *p* a piece of platinum, both immersed in dilute sulphuric acid; if they do not touch each other, scarcely any action will take place on the zinc, and none on the other metal; but if they touch, or if they are connected by a long wire of zinc or platinum, as represented in the figure, then action takes place; oxygen from the water combines with the zinc, and forms an oxide, which dissolves; and the equivalent of hydrogen is evolved, and appears against the platinum; whilst the connecting wire exhibits all those characters which show that a current of electricity is passing through it. The *direction* of this current is essentially connected with the chemical action on the zinc, and the evolution of hydrogen on the platinum, and may, at any time, be identified by comparing it with the electricity of the common machine. If the prime conductor and rubber of a machine be connected by a wire, the electricity is said, by a conventional expression, to be passing *from* the conductor through the wire *to* the rubber (see fig. 150, A, where *p* represents the conductor, and *n* the rubber); and, admitting that standard of reference, it is found in the experiment just described, that the current of electricity produced is from *p* through the wire to *z*. There are many other solutions, which, if used between the metals *z* and *p*, will cause a similar effect when the latter are connected by the wire, but the current is *always* in the same direction, and it is also always the zinc which enters into combination. Thus a solution of hydriodic acid, or of the iodide of potassium, will cause iodine to combine with the zinc, hydrogen will appear at the platinum, and a current of electricity will exist in the wire, but of weaker power than before.

* The impurities in common zinc seem to be the cause of the rapid action exerted upon it by diluted sulphuric acid, which oxidizes it with the evolution of hydrogen. Pure zinc, on the contrary, or, as Mr. Sturgeon has shown, zinc

which is superficially amalgamated with mercury, is not so acted on, and hence the advantage of using it in cases where the *ordinary* and the *voltaic* action require to be separately observed.

In producing this effect, there are two circumstances which seem to be essential, namely, the immersion of the zinc and platinum in the solution, and the metallic contact of the metals, either directly, or by means of the wire: if the contact be broken the current is stopped, and the action on the zinc ceases; or if the metals be taken out of the solution, the action on the zinc of necessity ceases, and again the current is stopped. Hence it became a question for many years, which, though much argued and experimented upon, has only recently been decided, whether it was the chemical action on the solution, or the contact of the metals, which was the real cause of the electric current, and other concomitant effects.

But now consider fig. 176, and let n and o be two vessels like to m (fig. 175), each containing dilute sulphuric acid and pieces of zinc and platinum, and let the two $z z$ be connected by a zinc wire, and the two $p p$ by a platinum wire: no chemical effects will occur, nor any current of electricity be formed; but the moment a wire of any metal is stretched from a to b , a current of electricity will run up it, dividing right and left, as is shown by the arrows, and oxidation of both zincs will take place, accompanied with the evolution of hydrogen at both platinum.

Consider this cross-wire as still retained in its place, but the dilute sulphuric acid removed from the vessel o , and replaced by a solution of the iodide of potassium. Still the currents will exist, as represented by the arrows; the chemical action will remain unchanged in the vessel n ; and in the vessel o , iodine will combine with the zinc, and hydrogen appear against the platinum. As yet the conditions both of *chemical action* and *metallic contact* exist, the cross-wire from a to b ensuring the latter; but now remove that wire, and instead of a cessation of action, the following change of effects will take place: the electric current from b across to a of course no longer exists; that from a through the vessel n to b will be weakened, and the chemical action in n much diminished; but the current from a through o to b will be actually inverted, and the chemical action in o will be inverted also, and the iodine will now appear in its free state against the platinum p , instead of combining with the zinc, and the hydrogen will appear at the opposite side.

Hence, not only is it proved that metallic contact is not necessary, and that chemical action is the cause of the phenomena, but also that two distant chemical actions may be opposed, and the weaker made to yield to the stronger; and thus, *electro-chemical excitation* and *electro-chemical decomposition* are shown existing together in the simplest manner as *cause* and *effect*.

If two distant chemical actions can be thus shown connected together in *opposition* to each other, so also can they be shown with equal simplicity associated in accordance with each other; and in this consists the *principle of the voltaic pile or trough*: for consider again the tendencies and directions of the two sets of forces, as indicated by the arrows, in the vessels n and o , fig. 176, and then divide the

connecting wires at *a* and *b*, connect the right-hand end of *a* with the left-hand end of *b*, and the right-hand end of *b* with the left-hand end of *a*, as in fig. 177, and then it will be seen by simple inspection, (what is found as a matter of fact,) that the forces in *p* and *q* aid and exalt each other, instead of exerting a mutual opposing action.

Fig. 178 is the representation of three such actions combined, and with 300 or 3000 the principle is the same; the pull on the general current being, as it were, aided by every recurrence of the zinc, and its vigour and intensity exalted.

In reflecting upon the source of electricity in voltaic arrangements, and upon the definite nature of its action, as shown in the experiments above quoted, it becomes almost impossible to doubt the *identity* of the cause of chemical and electrical phenomena, and from an attentive consideration of the manner in which the elements of electrolytes are evolved at the anode and cathode, the insufficiency of that theory which referred the phenomena of their decomposition to the mere *attractive powers of the poles* must be quite obvious: they must certainly be attributed to some specific action of the electric current, pervading the whole of its course through the electrolyte; and if we regard it, with Faraday, (*Phil. Trans.*, 1833, p. 696,) as “an axis of power having contrary forces, exactly equal in amount in contrary directions,” we may also assume that electro-chemical decomposition is produced “by an internal corpuscular action exerted according to the direction of the electric current, and that it is due to a force, either superadded to, or giving direction to the ordinary chemical affinity of the bodies present. The body under decomposition may be considered as a mass of acting particles, all those which are included in the course of the electric current contributing to the final effect; and it is because the ordinary chemical affinity is relieved, weakened, or partly neutralized by the influence of the electric current, in one direction, parallel to the course of the latter, and strengthened or added to in the opposite direction, that the combining particles have a tendency to pass in opposite courses.”

§ 14.—IDENTITY OF VOLTAIC AND COMMON ELECTRICITY.

THE phenomena of the voltaic pile are, upon a superficial view, so different from those of common electricity, as frequently to have been referred to a distinct cause, and although they were found, when more accurately compared, to present many analogies, it was long before they were allowed to be absolutely identical. Mr. Faraday was led to revise the experiments already made in reference to this question, and to devise many new illustrations of it: his results are published in the third series of his *Experimental Researches*. (*Phil. Trans.*, 1833, p. 23.) He has arranged electrical phenomena, for the purpose of this comparison, under two heads; namely, those connected with electricity of *tension*, and those connected with electricity of *motion*; the former includes attractions and repulsions at sensible distances: the latter (or the effects of electrical currents) includes the production of heat, magnetism, chemical decomposition, physiological phenomena, and the spark.

1. The *attractions and repulsions* produced by voltaic electricity, and so far identifying it with that of the common electrical machine, have been above described.

The escape of common electricity through rarefied air, is another effect due to its tension. On endeavouring to discharge a voltaic battery of 140 pairs of plates by approximated pointed wires, either with intervening air, or in a vacuum, no indications of a current, either by magnetic or chemical action, were obtained; but upon *heating* the air between the points, by the flame of a spirit-lamp, the current passed, so as to decompose iodide of potassium, and deflect the galvanometer in another part of the circuit. The arc of flame between charcoal points in air and in a vacuum is a similar phenomenon. Another proof of the tension and quantity of the electricity of the pile, is the charge of a Leyden battery, which may be effected by De Luc's column and by the voltaic battery.

2. As concerns *electricity in motion*, that of the voltaic apparatus produces heat, magnetism, chemical decomposition, shocks, and sparks, and in these respects the analogies with common electricity are complete. Of the *heating power* of common electricity, instances have been already given, both as relates to the common spark and to that of the Leyden jar or battery. For delicate experiments upon this subject, Mr. Harris's beautiful and sensible electrometer may be used. (*Phil. Trans.*, 1827, p. 17.) The production of *magnetism* by common electricity has also been satisfactorily proved, by the deflection of the galvanometer*, and by the simple experiment of affixing a steel needle at right angles to a wire through which the Leyden jar or battery is discharged, and which receives permanent magnetism.

The power of common electricity to effect *polar chemical decomposition*, was first shown by Dr. Wollaston (*Phil. Trans.*, 1801, p. 427), and has been amply and excellently verified by Faraday. Upon a glass plate (fig. 179) placed over, but raised above, a piece of white paper, so that shadows may not interfere, put two pieces of tin-

foil *a b*; connect one of them by an insulated wire *c* with the positive conductor of the machine, and the other by the wire *g* with the ground, or with the negative conductor: provide two pieces of fine platinum wire, bent as in fig. 180, so that the part *d f* shall be nearly upright, whilst the whole is resting on the three bearing points *p e f*: place these as in fig. 179; the points *p n* then become the decomposing poles. Place a large drop of *hydrochloric acid*, rendered blue by sulphate of indigo, so that *p* and *n* may be immersed in it at opposite sides, then send a current of electricity through it from a machine in good action, and *chlorine*, shown by its bleaching effects, will be evolved at *p*. This experiment is the counterpart of that with voltaic electricity, described in the first paragraph of page 311. Place a drop of

* By Mr. Colladon of Geneva, and in Faraday's experiments (*Phil. Trans.*, 1833, p. 30).

solution of *iodide of potassium* mixed with starch between the poles, and the current will evolve *iodine* at *p*. Put a drop of solution of *sulphate of copper* between the poles, and the current will then cause the precipitation of *copper* at *n**.

In all these experiments the direct passage of *sparks* must be carefully avoided. If *sparks* are passed over moistened litmus-paper, it is reddened; and if over paper moistened by iodide of potassium, iodine is evolved; but these effects must be carefully distinguished from those due to true *electrolytic* action, and must be cautiously avoided when the latter are sought for. The effect just mentioned is due to the formation of *nitric acid* by the combination of the oxygen and nitrogen of the air: the acid so formed, though very small in quantity, is in a high state of concentration, and therefore reddens the litmus-paper and decomposes the iodide. By moistening a very small slip of litmus-paper in a solution of caustic potassa, and then passing a succession of electric sparks over its length in the air, Mr. Faraday gradually neutralized the alkali and ultimately rendered the paper red, and on drying it he found that *nitrate of potassa* had resulted from the operation, and that the paper had become touch-paper. These experiments furnish simple, beautiful, and ready means of illustrating Cavendish's experiment of the formation of nitric acid from atmospheric air; and render it probable that the singular odour produced by the electric discharge, as when the electricity of a powerful machine is suffered to pass off by points, or in a succession of long and rapid sparks through the air, may be derived from the production of that acid†.

Though the above experiments amply demonstrate the identity of the decompositions effected by common and voltaic electricity, the true *polar* decomposition of *water* by the former has not hitherto been so effected as to collect an appreciable portion of oxygen and hydrogen, at the positive and negative poles: Faraday's experiments, however, leave no doubt as to the reality of such decomposition. When sparks or shocks are transmitted through water by fine metallic points, streams of gas arise from them‡, but they consist of oxygen and hydrogen at each pole,

* A curious experiment, which has been called *electro-chemical*, consists in tracing lines or devices upon a thin plate of glass covered with lac varnish, with the nob of a positively charged Leyden phial; *positive* electricity is thus communicated to the side touched, and corresponding lines of *negative* electricity are produced by induction, upon the opposite side. If we now suspend the glass plate insulated in the air, and blow upon it a finely-powdered mixture of sulphur and red lead, the *latter* only will adhere to those parts of the plate which are *positively* electrified. If we now blow the same mixture upon the other side of the plate, the *sulphur* alone will adhere to the parts which are *negatively* electrified. Thus the same lines will be traced upon both sides of the glass plate, but

with different coloured powders, the *positive* lines being *red* and the *negative* *yellow*. The cause of this appears to be, that when sulphur and red lead are triturated together, the *former* *acquires positive* and the *latter negative* electricity: hence the respective powders attach themselves to those surfaces which have an electricity *opposed* to their own.

† A similar odour is observed during the decomposition of water by the voltaic current.

‡ This experiment was first made by the associated Dutch chemists, Van Troostwijk, and Dieman, in 1789 or earlier; it was repeated by Dr. Pearson in 1797 (*NICHOLSON'S Jour.*, 4to., i.), and afterwards by Dr. Wollaston in 1801.—(*Phil. Trans.*)

and depend upon some cause, distinct from that which regulates the transference and final place of the evolved bodies, in cases of true electrochemical decomposition.

The *physiological effects* of the common electric current may be considered the same with those of voltaic electricity, account being taken of the *intensity* of the one, and the *duration* of the other.

With regard to the *spark*, that from common electricity rivals in brilliancy the splendid light of the voltaic discharge, but it endures for the fraction of an instant only. When the voltaic and the common spark are taken between amalgamated surfaces of metal, at intervals only, and through the same distance of air, the eye can distinguish no difference between them. A curious modification of the spark of a Leyden jar or battery is obtained, by causing the electricity to pass through some distance of water or other imperfect conductor, such as a piece of wet string, so placed as to form a part of the circuit: the spark is then yellowish, flamy, of sensibly longer duration than if the water had not been interposed, and is accompanied by little or no noise; if taken between pieces of charcoal it is extremely luminous and bright upon both surfaces of the charcoal: thus, whilst losing part of its usual character, it, in some degree, approximates to the voltaic spark. The *retardation* which the current of electricity suffers in being thus made to traverse water, is well illustrated by its effect in inflaming gunpowder. In attempting to ignite gunpowder by the discharge of a Leyden jar, unless it is finely powdered and rammed into a small tube or quill, and the discharge of a large jar or battery passed through it by points of iron wire, it is generally thrown

181

about but not exploded. Place the powder, for instance, in a small ivory mortar, of which fig. 181 is a section, and discharge a moderate-sized Leyden jar through it, so that the spark may pass between the interrupted wires *a a*; in this case the powder will be dispersed, and not ignited. But now repeat the experiment, placing a basin of water in the circuit, so that it may be interrupted by ten or twelve inches of that fluid, and the spark that passes under such circumstances will invariably fire the powder; or, the circuit may be interrupted

182

by a few inches of pack-thread well soaked in water, and the same effect will ensue. Fig. 182 is a representation of the arrangement: *a* is a Leyden jar with a piece of chain touching its exterior coating, and immersed at the other end into the shallow dish of water *b*, from the opposite side of which another chain issues, attached to one of the conductors of the mortar *c*: a chain is also attached to the opposite con-

ductors of the mortar *c*: a chain is also attached to the opposite con-

ductor; and the discharge is effected, by bringing the ball of the discharger *d* in contact with the nob of the jar *e*. When the circuit is entirely metallic, the passage of the electricity is apparently too rapid to kindle the powder, but it does so when retarded somewhat in its progress, by being made to traverse the water.

§ 15.—ANIMAL ELECTRICITY.

THERE are some remarkable instances of the generation of electricity in living animals, to whom the power seems to be given principally as a means of defence. Of these animals, the *Torpedo* or *Electric ray*, was noticed by the ancient writers on natural history: it inhabits the Mediterranean and North Seas; its weight, when full grown, is about eighteen or twenty pounds. When touched, it communicates a benumbing sensation, and by repeated contacts, gives a series of electric shocks.

The *Gymnotus*, or *Electric eel*, was first described in 1677, by M. Richer, who was commissioned by the French Academy to make some mathematical observations in Cayenne. It is a native of the warmer regions of Africa and America, inhabiting the larger rivers, especially those of Surinam. In Africa it chiefly occurs in the branches of the Senegal. These animals have been anatomically described by Mr. Hunter in the 63rd and 65th volumes of the *Philosophical Transactions*. Their electric organs consist of membranous septa, and are most abundantly supplied by nerves; their too frequent use is succeeded by debility and death. That these organs are not otherwise essential to the animals, is shown by their thriving after they have been removed.

The *Silurus electricus* is less perfectly known: it has been described by Broussonnet under the name of *Trembleur*. (*Histoire de l'Académie Royale des Sciences*, 1782.)

Walsh, Ingenhousz, Cavendish, Sir H. Davy, and Dr. Davy, (*Phil. Trans.*, 1773, 1775, 1776, 1829, and 1832,) have each experimented on this form of electricity, and their joint results leave no doubt as to its identity with common and voltaic electricity. Mr. Faraday, availing himself of a gymnotus brought to this country by Mr. Porter, and purchased by the proprietors of the Adelaide Gallery, has instituted new inquiries respecting the electric powers of this extraordinary animal. (*Phil. Trans.*, 1838.)

Humboldt, in his *Tableau Physique des Régions Equatoriales*, &c., has given some curious details respecting the electrical eel which inhabits the rivers and lakes of the low provinces of Venezuela and the Caraccas. It is met with most frequently in the stagnant ponds dispersed at intervals over the plains which extend from the Oronoco to the Apuré. The old road near Urutica has even been abandoned, on account of the danger experienced in crossing a ford, where the mules were, from the effect of the shocks, often paralysed and drowned. Even the angler sometimes receives a stroke conveyed along his rod and line. These eels are about six feet in length, and occasion a highly painful sensation, more resembling the effect of a blow on the head than the shock of a common electric discharge; a peculiarity of effect, referable perhaps to a great

quantity of electricity of small intensity. The following particulars given also upon the authority of Humboldt (*Edin. Review*, vol. xvi. p. 250) are too curious to be here omitted.

"The Indians entertain such a dread of the *Gymnotus*, and show so much reluctance to approach it when alive and active, that Humboldt found extreme difficulty in procuring a few to serve as the subjects of experiment. For this express purpose he stopped some days on his journey across the *Llanos* to the river Apuré, at the small town of Calaboze, in the neighbourhood of which he was informed that they were very numerous. But, though his landlord took the utmost pains to gratify his wish, he was constantly unsuccessful. At last he determined to proceed himself to the spot, and was conducted to a piece of shallow water, stagnant and muddy, but of the heat of 79 degrees, surrounded by a rich vegetation of the great Indian fig-trees and odoriferous sensitive plants. Here he soon witnessed a spectacle of the most novel and extraordinary kind: about thirty horses and mules were quickly collected from the adjacent savannahs where they run half wild. These the Indians drove into the marsh. The *gymnoti*, roused from their slumbers by the noise and tumult, mount near the surface, and swimming like so many livid water-serpents, briskly pursue the intruders, and gliding under their bellies, discharge through them the most violent and repeated shocks. The horses, convulsed and terrified, their mane erect, and their eyes staring with pain and anguish, made unavailing struggles to escape. In less than five minutes two of them sunk under the water and were drowned. Victory seemed to declare for the electric eels. But their activity now began to relax. Fatigued by such expense of nervous energy, they shot their electric discharges with less frequency and effect. The surviving horses gradually recovered from the shocks, and became more composed and vigorous. In a quarter of an hour the *gymnoti* finally retired from the contest, and in such a state of languor and complete exhaustion, that they were easily dragged on shore by the help of small harpoons fastened to cords."

The *gymnotus* experimented with by Mr. Faraday gave a powerful shock when one hand was placed near each extremity of the fish. By the proper application of conductors it affected the galvanometer, and made a magnet; polar decomposition of iodide of potassium was easily effected by it, with such phenomena as indicated a current passing from the anterior to the posterior parts of the animal; and, lastly, the spark was obtained.

Those who are fond of supposing that electricity is an agent in certain processes of vitality, have referred, in favour of their hypothesis, to certain other cases of its production by arrangements of different organic substances. If the hind legs of a frog be placed upon a glass plate, and the crural nerve dissected out of one made to communicate with the other, it will be found, upon making occasional contacts with the remaining crural nerve, that the limbs of the animal will be agitated at each contact. Hence some physiologists suppose that electricity may be concerned in some of the most recondite phenomena of life, and experiments have been made tending to confer some probability on this idea.

"The principle once established, that there may exist in the animal

economy a power of determining the developement of electric excitement capable of being transmitted along the nerves; and it being ascertained by numerous and decisive experiments, that the transmission of voltaic electricity along the nerves of even a dead animal is sufficient to produce the most violent muscular action, it became an easy step to refer the origin of muscular motion in the living frame to a similar cause, and to look to the brain, a wonderfully constituted organ, for which no mode of action possessing the least plausibility had ever been devised, as the source of the required electrical power."

Sir John Herschel*, from whom I have quoted the last paragraph, extends his ideas upon this subject in the following note. "If the brain be an electric pile, constantly in action, it may be conceived to discharge itself at regular intervals, when the tension of the electricity developed reaches a certain point, along the nerves which communicate with the heart, and thus to excite the pulsations of that organ. This idea is forcibly suggested by a view of that elegant apparatus, the dry pile of De Luc, in which the successive accumulations of electricity are carried off by a suspended ball, which is kept, by the discharges, in a state of regular pulsation for any length of time. We have witnessed the action of such a pile maintained in this way for whole years, in the study of the above-named eminent philosopher. The same idea of the cause of the pulsation of the heart appears to have occurred to Dr. Arnott, and is mentioned in his useful and excellent book on Physics, to which, however, we are not indebted for the suggestion, it having occurred to us, independently, many years ago."

§ 16.—THERMO-ELECTRICITY.

In 1832 Professor Seebeck of Berlin discovered this form of electricity: he found that a bar of antimony, (fig. 183,) *a*, with a piece of brass wire twisted round one end of it *b*, and attached to the other in the form of a loop *c*, when heated by the flame of a spirit-lamp at the contact of the metals *b*, caused the deflection of a magnetic needle placed at *d*.

But two metals are not necessary to this effect, for if one end of the galvanometer-wire be cooled and the other heated, especially if it be of platinum, the needle will deviate when they are brought into contact. If a bar of bismuth be soldered to one end of the galvanometer-wire and a bar of antimony to the other, no effect is produced on bringing the two bars into contact when they are both of the same temperature; but if one of them be either heated or cooled, and then made to touch the other, the flowing of an electric current is immediately indicated.

This current of electricity is rendered more evident by the following modification of the arrangement; in which *a* (fig. 184) represents four bars of antimony, soldered to four bars of bismuth *b*. If the extremities at *c* be now united by perfect metallic contact, as by dipping them into

* *Preliminary Discourse on the Study of Natural Philosophy*, p. 342.

mercury, and *heat* and *cold* applied alternately to the junctions of the two metals, an electric current will be put into motion in the direction of the darts, which will deflect a magnetic needle from its meridian, placed immediately over or under any part of the circle, and which may be rendered more evident by the deflection of the galvanometer properly connected with the extremes *c.*

The term *stereo-electric* has been also applied to this current, implying its production in *solid* bodies independent of a fluid (from *στερεος*, *solid*) as opposed to the voltaic or *hydro-electric* current.

By forming circuits of the metals taken in pairs, they may be arranged in a series descending from the extreme negative, which is bismuth, to the extreme positive, antimony. Their thermo-electric properties have no correspondence either with their voltaic relations, or powers of conducting heat, or electricity; neither do they accord with specific gravity, nor atomic weights. These relations are shown in the following table from Professor CUMMING'S *Manual of Electro-dynamics*, every substance in the thermo-electric series being considered as negative to all below, and positive to all above: hence, any metal in the upper part will form a circuit with all below it, similar to, though less powerful than, that of bismuth and antimony. Dr. Roget, in his treatise on *electro-magnetism* (in the *Library of Useful Knowledge*, p. 94) inverts these terms, and says, that in the following thermo-electric series, every metal is positive to those below it, and negative to those above: in the deflection of the needle, bismuth and antimony bear the same relation to each other as silver and zinc in the single voltaic circuit, hence it flows from the antimony to the bismuth; the latter, therefore, corresponds to the positive, and the former to the negative element: in this acceptation, therefore, Dr. Roget is correct: in the compound voltaic series, when the zinc end is called the *positive*, and the copper the *negative* pole, the terms are of course reversed.

According to the experiments of Nobili, thermo-electric circuits may be formed with substances of lower conducting powers than the metals. He made small cylinders of porcelain clay, and wrapped round the end of each some cotton steeped in a conducting liquid, which served to place them in direct communication with a galvanometer: one of the ends was reduced to a point, and after heating it to redness by a spirit-lamp, was pressed on the cold extremity of the other cylinder, when a current was established from the hot to the cold part of the arrangement.

All the phenomena of the thermo-electric current show it to depend upon considerable *quantity* opposed to very feeble *intensity*; it is indeed apparently sluggish even in its passage through metals; in that respect therefore directly opposed to common electricity. It is not easily cognizable by any means except the deflection of the magnetic needle, and has not hitherto been made to produce heat, or light, or chemical effects, though it is said to have convulsed the limb of a frog (NOBILI, *Bib. Univ.*, xxxvii., 15). A beautiful application of a thermo-electrical apparatus has been made by Nobili and Melloni (*Bull. des Sciences*, 1831), and employed by the latter in his experiments on radiant heat: they constructed a *thermo-electric pile* of thirty-six pairs of small plates of bismuth and antimony, and attached it to a delicate galvanometer: it was so susceptible of changes of temperature, and, therefore, so delicate a *thermoscope*, as to be affected by the warmth of the hand held at a considerable distance from it: in experiments on radiant heat it is rendered additionally sensible by covering one of its faces with a thin coating of lamp-black.

Some theorists have adduced the phenomena of thermo-electricity in support of the contact-theory of the pile, but Faraday's arguments and experiments prove that the two series of phenomena are perfectly distinct; a conclusion also sanctioned by the researches of Becquerel. (*Phil. Trans.* 1840, p. 122, *Ann. Ch. et Ph.*, xli. 355, xlv. 275*.)

* Some extraordinary phenomena, in some respects the converse of those which we have called thermo-electric, have been observed by Peltier. When a weak electric current from a single circuit is transmitted through a bar of equal lengths of bismuth and antimony soldered together, from the antimony to the bismuth, heat is evolved at the point of junction, but if in the contrary direction, cold. The effects are appreciable by placing the bulb of a delicate thermometer in a hole at the point of junction; it rises 80° in the first case, and sinks to 6° in the second. If the bar be placed on thawing ice, a little water may thus be frozen in the cavity made for the thermometer.

"This production of cold by the voltaic current may be demonstrated also in a striking way by the secondary thermo-electric current which it tends to generate. Let a bar of bismuth 4·5 inches long, 0·4 inch square, and a similar bar of antimony be placed across each other at

right angles, and mortice half their thicknesses into each other at the place where they cross, and solder them together with tin. On connecting two of their ends with a galvanometer, and sending a current through the others, a deflection of the needle will take place on one side from the current generated by the change of temperature; when the direction of the current is reversed, the needle will be deflected in the contrary direction, proving that an opposite change of temperature has taken place from the reversal of the current. That this secondary current is not due to any diversion of the primary current, may be proved by connecting the two ends of the same bar with the galvanometer, and sending the current through the other bar, when no effect will be produced.

"These effects of what may, perhaps, be designated as *electro-thermancy*, which we owe to M. Peltier, are the converse of those of thermo-electricity." DANIELL'S *Introduction*, § 800.

§ 17.—MAGNETISM.

THERE are certain native oxides of iron which are termed *magnetic iron ores*, and which have the remarkable property of attracting iron filings: when, or by whom this property was originally discovered, is not known; but the Greeks called the iron ore *μαγνητος*, from the name, as it is said, of a shepherd, who first observed it. Pliny describes it under the name of *magnes*, a term said to be derived from Magnesia, a province of Lydia, where this ore abounded.

If a bar of *tempered steel* be rubbed in a certain direction with this native magnet, or *loadstone*, it is itself rendered *permanently magnetic*, and acquires properties similar to those of its source.

There are other means by which magnetism may be temporarily or permanently conferred on iron, and even on other metals; but steel is the only substance (with the exception of nickel) which receives and retains it*: of these sources of magnetism, *electricity* is among the most remarkable, and a new branch of science has arisen out of the phenomena thus presented, called *electro-magnetism*; it is to render the details upon this subject intelligible, that I shall here briefly describe the leading properties of the common magnet, without, however, entering into the extended and interesting theoretical reasonings which have been founded upon them, and which refer to the ultimate *cause* of this important and recondite property†.

The most obvious properties of the magnet are—1, polarity; 2, attraction of iron; 3, attraction and repulsion of another magnet; and, 4, the production of magnetism in iron by induction.

1. POLARITY.—If a slender bar, or needle, of steel rendered magnetic, be poised on a central point, or suspended by a thread so as to have perfectly free motion in a horizontal plane, and to be uninfluenced by neighbouring ferruginous bodies, it will for a time oscillate to and fro, and ultimately settle in a position nearly *north and south*; and if again disturbed, it will vibrate, and again assume the same direction, which, therefore, is called the *magnetic meridian*; this constitutes *magnetic polarity*, and the ends of the needle pointing north and south are usually called its *north and south poles*.

2. ATTRACTION OF IRON.—On bringing either pole of a magnet near a small piece of iron, it will be attracted; and if iron-filings are used, they will cluster about the poles. From the way in which the filings

* In making a magnet, a bar of steel is rubbed in *one direction* by a magnet: great care is necessary in observing the direction, and not reversing it, for a powerful magnet may be presently unmade, or rendered unmagnetic, by passing a magnet over it in an opposite direction to that in which its magnetism had originally been conferred. A good abstract of the methods of making artificial magnets, will be found in the *Library of Useful Knowledge*, (Magnetism, p. 41.)

† The compendium of magnetism and electro-magnetism by Dr. Roget, in the *Library of Useful Knowledge*, Professor Cumming's *Manual of Electrodynamics*, the articles on "Magnetism" in the *Encyclopædia Metropolitana*, and the papers of Professor Faraday in the *Phil. Trans.*, are the authorities to which I refer those who wish for information upon the above subjects, and for particulars incompatible with the object of this *Manual*.

adhere, it appears that in the common magnetic needle, the great attractive force is near its extreme ends, or at its *poles*, and that it diminishes towards the centre, at or near which no attraction exists. These attractions are *mutual*, that is, the iron attracts the magnet, and *vice versâ*.

3. ATTRACTION AND REPULSION OF ANOTHER MAGNET.—If we bring the pole of another magnet near that which is poised, we shall find that if the two *similar* poles be presented to each other, they exhibit a mutual *repulsion*; but that the *dissimilar* poles, mutually attract each other; here, therefore, we observe an analogy between magnetism and electricity, for *between similar powers there is repulsion, and between dissimilar powers, attraction*.

4. MAGNETIC INDUCTION.—If a bar of iron be brought near a magnet, the iron acquires temporary, or *induced magnetism*; and here again an analogy to electric induction will be observed. Let *a*, fig. 185, represent a bar magnet, and *b* a bar of unmagnetic and *soft iron*, brought to within a short distance of *s*, the south pole of *a*: it will then be found, that whilst in this situation *b* is a magnet, the poles of which, *n' s'*, are opposed to those of *a*, and consequently attraction subsists between *s* and *n'*; and if a second piece of soft iron, *c*, be placed near *b*, it will also become polar, *n''* being its north, and *s''* its south pole, consequently *s'* and *n''* will attract each other; on withdrawing *a* all magnetic properties in *b* and *c* immediately vanish.

The experiment may be modified, as shown in fig. 186, where *a* is the magnet, *b* a short bar of iron, *c* an iron key, and *d* several iron bullets; the magnetism in *b*, *c*, and *d* is here *induced* by *a*; the respective north and south poles are produced and attracted as before, and each bullet acquires a similar polarity by which they are mutually held together; if *a* be now carefully withdrawn to within a very short distance of *b*, *b c* and *d* will still retain their induced magnetism; but, on removing *a* to a greater distance, *b c* and *d* will drop asunder, and all magnetism disappear. When, therefore, a cluster of iron-filings is held by the pole of a magnet, each particle of iron is polar, and the whole is an analogous result of induction.

It has been observed that when a magnet is acting upon a piece of soft iron by induction, as in the case of *a* and *b*, fig. 185, the power or intensity of the magnetism in *a* suffers an increase, and its poles, whilst under induction, have a greater attractive power, and will sustain a greater weight than when that influence is removed.

According to Mr. Harris, the intensity of magnetic power developed by induction in an iron bar, is inversely as the distance of the inducing pole from the adjacent end of the bar on which it acts; and the intensity of magnetism induced on the remote end of the bar is, with the same inductive power acting on the nearer end, inversely as the length of the bar. (*Trans. R. S. Edin.*, 1829.)

When a magnet, instead of being applied as in fig. 185 to the *end* of an iron bar, is applied to its *centre* (fig. 187), both the extremities assume

and every part of the *circumference* will acquire the properties of a weak *north pole*, as in fig. 188. The following simple experiment furnishes a useful illustration of the phenomena of induction and of magnetic

attraction and repulsion. Attach two short pieces of iron-wire to a thread, and suspend them opposite to each other as in fig. 189. Then bring the pole of the magnet, *s*, slowly towards them; the wires will gradually *diverge* because they become magnetic by induction, and their north poles *nn*, and south poles *ss*, are thus rendered similarly magnetic; but, on advancing the pole of the magnet nearer to the wires, as in fig. 190, its attractive power overcomes the repulsion that exists between the ends *nn*, and they are consequently *drawn towards s*, while the repulsion between *ss* is increased. It is upon this principle that the

filaments of polar iron-filings adhering to the pole of a strong magnet, diverge, or are repelled by each other.

All the magnetic properties induced in soft iron cease when it is heated to bright redness; so that if we heat the whole of a small iron bar up to that point, and then bring it near a magnetic needle, it will not affect it; as soon as it is cooled down to a common red heat the magnetism returns, and is stronger than in the cold iron: but there is one particular period during cooling, between the white and red heat, at which the induced polarity is inverted; or in which the iron attracts the needle the contrary way to what it does when it is cold. (BARLOW, *Phil. Trans.* 1822, p. 118.) We also find that the permanent magnetism of a steel needle is diminished by a moderate heat, and that a red heat totally destroys it. Mr. Faraday found the induced magnetism of nickel to be destroyed by a heat below redness, and conceives it probable that the unmagnetic metals are, at *common temperatures*, in the same relation to magnetism as iron at a *bright red heat*, and that at some very low temperature they would exhibit a similar relation to magnetism with that belonging to iron at common temperatures*.

It is obvious, from the position assumed by the magnetic needle when freely moving in an horizontal plane, that there is some attractive force in the earth, which causes it to assume a constant direction, and that what we have termed the north pole of the magnet, is attracted towards the north pole of the earth, and its south pole by the south pole

* In reference to the influence of *temperature* upon magnetism, see a paper by Mr. Christie. (*Phil. Trans.*, 1825.)

of the earth; and hence it is inferred, according to the above stated law of magnetic attraction, that the poles of the earth are in an opposite magnetic state to those of the needle.

We find that the earth has a further influence upon an artificial magnet, which is only rendered evident when it is so suspended as to move freely in every direction. Under these circumstances, and in our latitudes, the *north pole* of the needle is attracted *downwards*, as well as to the north, and assumes a position almost vertical, that is, making an angle with the plumb line of about 20° : this inclination to the horizontal plane is called the *dip of the magnetic needle*.

These, and other phenomena, have been ascribed to the influence of a magnetic power in the earth: Dr. Halley regarded the globe as constituting a great magnet having four poles, two to the north and two to the south, at considerable and unequal distances from the poles of the earth. (*Miscellanea Curiosa*: as quoted by Dr. THOMSON on *Heat and Electricity*, p. 546.) Two of these poles, one to the north and one to the south, are supposed to be *fixed*, the other two *moveable*. M. Hansteen has adopted a similar hypothesis, and the changes in the direction and dip of the needle, or the *variation of the compass*, have been referred to such causes*: these, however, are subjects which it is unnecessary to pursue here, and I have only thus far adverted to them, to remind the student of the necessity of taking the influence of the earth's magnetism into the account, in all cases where we speak of this power, and to explain another cause of the temporary and permanent production of magnetism in iron and steel, resulting exclusively from the earth's influence.

When a bar of soft iron is held nearly *vertical*, or in the *direction of the dipping needle*, its ends are no longer *indifferently* attractive of a poised magnet; but (so long only as it continues in or near that position) it is *polar*, the *lower end* of the bar being a *north pole*, and the *upper end* a *south pole*, and it affects the magnetic needle accordingly. We now need only place the bar in a *horizontal* position, and both ends then *indifferently* attract the poles of the needle; or in other words, the induction of the earth is *neutralized* and vanishes. It is not uncommon to find bars of steel, which have long remained in a nearly vertical position, permanently magnetic; that is, *polar*; this is often the case with the poker and tongs: and there is a very curious mode of making a magnet, dependent upon the same cause, which consists in holding a bar of steel in the direction of the magnetic dip, and striking it whilst in that position, a few smart blows with a hammer: the upper and lower ends then become south and north poles. If a bar of steel already magnetized, and not in this position, be similarly treated, it loses its magnetism: and hence the necessity of caution in using good magnets, to

* In the year 1660, the magnetic needle in London pointed exactly north and south, London being at that time in the *line of no variation*. Before that period, the variation was to the east, but after the year 1660, the variation became westerly, the line of no variation therefore has been progressively but slowly moving in a westerly direction, and has

now passed to North America. At London, the westerly variation continued to increase till 1818, when it amounted to $24^{\circ} 30'$; this appears to have been its maximum, and since that time it has somewhat diminished. The *dip* has undergone corresponding changes: in 1773 the dip was $72^{\circ} 19'$; in 1830, $69^{\circ} 38'$.

avoid striking them or letting them fall, by which their magnetism is more or less weakened.

The manner in which the magnetic force emanates from the poles of a magnet is well illustrated, by placing two magnetized bars with their opposite poles about an inch asunder, under a sheet of writing-paper, and then sifting iron filings upon the paper; they will assume a peculiar and beautiful arrangement, showing the direction of the *magnetic curves*, (some-

what as in the annexed figure 191,) which is perfected by gently shaking or tapping the paper to assist their polar adhesions. If we place a piece of soft iron between the poles, and within the curves at *c*, it becomes, as already explained, magnetic, by induction. These curves or currents are well shown between the poles of what is commonly called a *horse-shoe magnet*, in which the magnetized bar is bent into that form (fig. 192). *ns* are its north and south poles; *s'n'* are the *induced* north and south poles of a bar of soft iron, commonly called the *holder*, and which, when applied to the magnet, is powerfully attracted. A scale may be conveniently attached to the holder for determining the power of the magnet by the weight which it will sustain.

As iron and steel, when free from magnetism, are attracted only in consequence of induction, it follows that the degree of susceptibility to induction may be measured by the attraction which results from this property. With this view, Mr. Barlow (*Phil Trans.*, 1822, p. 117) made a series of experiments to ascertain the relative attraction which different species of iron and steel had for the magnet, and obtained the following results, the relative magnetic power of each substance being expressed by numbers.

Malleable-iron	100	Hard blistered-steel	53
Soft cast-steel	74	Hard shear-steel	53
Soft blistered-steel	67	Hard cast-steel	49
Soft shear-steel	66	Cast-iron	48

Mr. Hatchett found that the *protosulphuret* and *phosphuret* of iron, were susceptible of receiving and retaining magnetism; in this respect, therefore, they resemble the *protoxides* of that metal, and the *protocarburet*, or steel: the peroxides, the persulphurets, and plumbago, natural and artificial, are not magnetic: his suggestions, in reference to the magnetic properties of the above compounds, and of the circumstances which interfere with those of the varieties of cast-iron, deserve further consideration.—(*Phil. Trans.*, 1804.)

§ 18.—ELECTRO-MAGNETISM*.

HAVING, in the preceding section, defined the meaning of the term *magnetism*, we now proceed to examine the *evolution of magnetism* by

* The reader who may be desirous of historical details and references to authors, upon this subject, may advantageously consult Mr. Faraday's "Historical Sketch of Electro-magnetism," in the *Annals of Philosophy*.—(New Series. ii.)

electricity; this important discovery was made in 1819, by Professor Ørsted of Copenhagen.

All the effects we are about to describe depend entirely upon *electricity in motion*, or upon *electric currents*, and are directly proportionate to the *quantity* of electricity: nothing of the kind is produced by electricity of *tension*, nor are they apparently increased by increasing the *intensity* of the current. Hence, for their developement, voltaic electricity is infinitely more effective than common electricity; and in the voltaic arrangements employed, all depends upon the *surface of the plates*, and nothing upon the number of their alternations: hence also *perfect metallic contact* of the conductors employed must be observed.

When a wire transmitting the volta-electric current (and which may be called the *connecting wire*) is brought near a common magnetic needle, it has the power of attracting and repelling it, in obedience to very peculiar laws. If a magnetic needle be left to take its natural direction, and then a straight portion of the connecting wire be brought *above and parallel to it*, the end of the needle which is next the negative pole of the battery moves towards the *west*, and that, whether the wire be on the one or other side of the needle, so that it be above and parallel to it. If the connecting wire be sunk on either side of the needle, so as to come into the *horizontal plane* in which the needle is allowed to move, there is no motion of the needle in that plane, but the pole of the needle attempts to move in a *vertical circle*, and but for the imperfect suspension, and the earth's magnetism, would do so. When this wire is on the *east* of the needle, the pole next the negative end of the battery is *elevated*, and when on the *west* of the needle it is *depressed*. If the connecting wire be now sunk *below the level of the needle*, similar attractions and repulsions take place, but in opposite directions to those followed when it is above. The pole of the needle opposite the negative end of the battery now moves *eastwards*, whatever the position of the wire, so that it be restricted as above.

In discussing the relations of the electric and magnetic currents indicated by this experiment, it may be useful, instead of indiscriminately using the terms north and south, east and west, and negative and positive, to employ them in reference to the following position. If we stand with the face towards the north, and the current of electricity pass in the same direction, that is from the south to the north (parallel with the magnetic meridian) then the magnetic needle, when *above* the electric current, will turn to the *left*, or to the *west*; and *below* the current, to the *right* or to the *east*: its north pole will be *elevated* when on the *east* side of the current, and *depressed* when upon the *west*, and will have a tendency, therefore, to *revolve* round the electric current in a direction from *east to west*, or from *right to left*.

In the diagram (fig. 193) the electric current is supposed passing through the conducting-wire *p n* (1), in the direction *s N*, in which case the magnetic needle, placed *above* it, has its marked or north pole deflected towards the *west*, and (as in 2), placed *below* it, towards the *east*.

The following contrivance of Dr. Roget is useful in assisting the memory respecting the details of these affections. A B (fig. 194) is a slip of card, on each side of which a line $a b$ is drawn along the middle of its length, the end a being marked +, the end b —, and the centre c , being crossed by an arrow at right angles to it, directed as in the figure. Through the centre and at right angles to the plane of the slip of card, there is made to pass a slender stem of wood, at the two ends of which are fixed in planes parallel to the slip of card A B, the circular discs of card, marked respectively with the letters N and S, and with arrows parallel to, but pointing in a contrary direction to the one at c . The same marks must be put on the reverse of each of the three pieces of card, so that when held in different situations they may be seen without turning the instrument.

If the line $a b$ be supposed to represent the galvanic wire (the direction of the current of electricity being denoted by the signs + and —, at the ends of the line), the arrow at the centre will point out the direction in which it tends to move, when under the influence of the north pole of a magnet, situated at N; or of a south pole situated on the other side at S: and *vice versâ*, the arrows at N and S will indicate the directions in which the north and south pole, respectively, tends to revolve round the galvanized wire in its vicinity, with relation to the direction of the current of electricity that is passing through it.

It must be observed that the poles N and S are here not considered as in connexion with each other, or as forming parts of one magnet: their operations are exhibited singly, and quite independently of each other. The advantage of this little instrument consists in its being capable of being held in any situation, and thus easily adapted to the circumstances of any fact or experiment of which we may wish to examine the theory.

All substances, which admit of the transfer of the electric current, exhibit similar phenomena; but the best conductors, or those which appear to afford the least resistance to the current, are those which become most powerfully magnetic: the metals, therefore, stand in the order of their electro-conductive powers; and when liquids are used, the best conductors among them are those by which the magnetic needle is most powerfully affected. The electric current itself, when passing through rare air, exhibits the same phenomena. Every part of the conductor, of course, exhibits similar phenomena, and everything through which the current is passing; the connecting-wire, therefore, so long as the current is passing through it, is everywhere attractive of iron-filings, and the voltaic pile itself acts upon the needle, precisely as the connecting-wire.

From the manner in which the needle is affected when placed parallel to either side of the electric current, it was inferred that a current of magnetism (as it may be termed) is put into motion by the electric current, so as to circulate, as it were, at right angles to the latter: hence

Dr. Wollaston termed it *vertiginous magnetism*; or, as Mr. Barlow expressed it, the magnetic force exerts a *tangential* action. Let us, therefore, suppose fig. 195 to represent the conductor through which the electric current is passing from end to end in the direction of the dart *p*, then the small arrows will represent the direction of the circulating current of magnetism. In fig. 196 both currents are moving in the opposite direction. Supposing the wires or conductors above represented placed side by side and parallel to each other, they will obviously be *magnetically repulsive*, because similar magnetic polarities (as shown by the horizontal darts) are opposed to each other; but if we invert either conductor, or, what amounts to the same thing, change the direction of the electric current in it, they will then become *magnetically attractive*, because the dissimilar magnetic polarities are then opposed to each other. So that two wires in which the electric current is passing in the same direction are magnetically attractive; and two wires, in which the electric current is passing in opposite directions, are magnetically repulsive.

Impressed with this view of the relative motions of the electric and magnetic currents, Mr. Faraday conceived that the pole of the magnet ought to revolve about the electric conductor, and the electric conductor about the pole of the magnet, and by the following very ingenious apparatus he succeeded in the experimental verification of the theory*.

Fig. 197 represents two glass vessels, A and B, placed side by side, with their appendages. In A the motion of a magnetic pole round the connecting-wire (or electric current) is produced, and in B the connecting-wire moves round the pole of the magnet. That a current of electricity may be established through the cup A, a hole is drilled at the bottom, and into this a copper pin is ground tight, which projects into the cup, and is rivetted below to a small round plate of copper, which forms part of the foot of the vessel, and communicates with the connecting-wire *a*. A small cylindrical and powerful magnet *b* has a piece of thread fastened to one of its poles, by which it is attached to the copper pin at the bottom of the cup, and so adjusted, that when the cup is full of clean mercury, the free pole *b* floats almost upright at the surface. The stem of the vessel B is tubular, and a copper socket is attached to its copper foot, in connexion with the conductor *a'*, which holds the magnet, *b'*, projecting above the centre of the mercury. In these cups of mercury, therefore, the two magnets are similarly arranged,

* Mr. Faraday's original papers on this subject will be found in the *Quarterly Journal of Science and the Arts*, vol. xii.,

pp. 75, 186, 283, and 416. The date of the first is September 11, 1821.

except that in A the pole is moveable, and in B, fixed. *c* is a brass stem and cross-wire prolonged by a smaller wire into the cup of mercury A, on one side, and on the other into B, but on this side the conducting-wire *c* is suspended by a loop, so as freely to move round the end of the magnet *b'*. If *a* be now connected with the positive, and *a'* with the negative, voltaic wire, so that the electric current may traverse the apparatus in the direction of the darts, the moveable magnetic pole *b* will revolve about the fixed conductor; and the moveable conductor *c* will revolve about the fixed magnetic pole *b'*. On changing the direction of the electric current, that of the respective rotatory motions will also be changed.

Since this discovery, a great variety of rotatory electro-magnetic apparatus has been suggested and contrived, in which the electric and magnetic currents are mutually made to produce the revolutions of conductors about each other, and about their own axes, in most of which volta-electricity, and in some, thermo-electricity is used: of these, a good account will be found in the *Library of Useful Knowledge* already quoted, and in Mr. F. Watkins' popular sketch of electro-magnetism and electro-dynamics.

Referring to the statement just given of the manner in which the magnetic needle is affected by the electric current, the construction and use of that valuable instrument the *galvanometer*, which has been so often referred to, and which was originally suggested by Schweigger, will easily be understood. In its simplest form it consists of a magnetic needle, so poised as to be affected by an electric current passing above and below it, as in fig. 198, where *P* and *N* are two small copper cups, each containing a little mercury, for the purpose of connexion with the voltaic or other source of the electric current, which moving in opposite directions in the upper and lower portions of the wire, as shown by the darts, will conspire in both cases, to deflect the needle from its natural position, in the same direction, and to bring it into a position nearer to a right angle to the plane of the wires. To multiply this effect, and to render the instrument a more susceptible indicator of feeble electric currents, the convolutions of the wire are multiplied, and the

lateral transfer of electricity prevented, by coating it with silk, or sealing-wax; and instead of supporting the needle upon a pivot, it is suspended by a fine thread of silk, or, as suggested by Professor Ritchie, (*Phil.*

Trans., 1830, p. 218,) by a filament of spun-glass; the sensibility of the instrument is further increased by employing two needles, one above and the other within the coil, and placed parallel, but with their poles opposed, so as to neutralize the magnetic influence of the earth: to this instrument a divided circle is so attached as to enable the observer readily to read off the deviation. This form of galvanometer, or *electro-magnetic multiplier*, is shown in fig. 199 (in section), *ns* is the lower needle, surrounded by the coil of wire, and connected with the upper needle, *s n*, by an intermediate piece of straw, which passes through the upper part of the horizontal coil, and through the circular card above it, on which the graduated circle is drawn, and is attached to the torsion filament suspended from a screw, supported by the frame of the instrument*.

From the direction of the *magnetic* as opposed to the *electric* current, it is obvious that an iron or steel needle placed *transversely* to the connecting-wire, as in fig. 200, will acquire magnetic *polarity*, and that if *p n* represent the conducting-wire, and *s n* the needle, the nature of its polarity will depend upon its being *above* or *below* the electric current. But in thus making a magnet, either temporarily of iron, or permanently of steel, a great increase of power is obtained by winding the connecting-wire (which in this case must be covered with silk to prevent contact of the metallic surfaces) round the iron bar, in the form of a close spiral, the effect of which will be, in the first place, a close assimilation in the coil itself to a magnetic needle, and in the next a great increase in the general magnetic effect, as will be apparent from the following considerations. Let *p n*, fig. 201,

represent a straight conducting-wire, in which an electric current is passing in the direction of the large dart; the small darts, will then show the direction of the magnetic influence or vortex: if we now coil this wire into a spiral, the magnetism will tend the same way in each convolution, as in fig. 202, where the connecting-wire, (in which the direction of the *magnetic* current is indicated by the darts,) is supposed to be wound spirally round a glass tube, and where *ns* represents a

steel bar in the axis of the tube and spiral, in which case it becomes a powerful magnet. If a glass tube thus surrounded by a coil of wire traversed by the electric current be held *vertically*, it will actually draw up an iron needle and retain it in its axis, against the force of gravity.

If such a wire be wound round a bar of soft iron, it is rendered a very powerful magnet during the passage of the electric current; and by employing a bent bar of iron, (fig. 203,) and connecting the extremes of the wire *p* and *n* with the positive and negative mercurial cups of the

* The various forms of the galvanometer have been improved in their mechanical arrangement by Mr. Watkins, of Charing-cross.

single voltaic plates shown in fig. 149, a most powerful form of the horseshoe magnet is obtained.

From the description of the heliacal or spiral arrangement just given, we can understand how a voltaic magnet may exactly resemble a common magnet, in its obedience to other magnets and to the earth's polarity. This is well shown in De la Rive's *floating electro-magnet* (fig. 204), in which the copper cup and zinc plate forming the simple voltaic circle, is inserted into a glass cylinder adapted for floating in water: the ends of the spiral being soldered to the wires *N P*. Here the spiral represents the magnetic needle, placing itself in the magnetic meridian, and being obedient to another magnet brought to either of its poles.

We have an interesting modification of this apparatus in De la Rive's single or circular magnetic coil, which may be constructed as follows. *z c* (fig. 205) are a zinc and copper plate attached to a piece of cork sufficient to float the whole apparatus, with the plates immersed in a basin of dilute sulphuric acid. A copper wire is soldered to the copper plate, and being covered with silk thread is formed into six or eight circular convolutions, its other end being soldered to the zinc plate. When this arrangement is floating in dilute acid, a current of electricity traverses the circles of wire in the direction of the darts, and a magnet *n s* presented horizontally to its axis causes the ring to move towards it, till it reaches its centre, where it pauses in a state of equilibrium. If we now withdraw the magnet, and reversing its poles, (whilst the ring is held in its first position,) pass it half way through the ring, it may possibly again remain in equilibrium, but the slightest change of position causes it to move with an accelerated velocity towards the pole nearest to it, and getting clear of the magnet is first repelled, then turning round so as to present its opposite face to the magnet, it is attracted, and passing again over the pole of the magnet, rests in equilibrium at its centre, or at what may be called the magnetic equator. In the first position it was equally attracted by the two poles, and in the second equally repelled.

§ 19.—MAGNETO-ELECTRICITY*.

UNDER this term, I shall describe another branch of electrical science, vying in interest and importance with the discovery of Ørsted detailed in the last section, and being in fact the converse of it, namely *the production of electricity by magnetism*, for which we are exclusively indebted to Mr. Faraday. (*Phil. Trans.*, 1831.)

From the statements in the last section, it is evident that magnetism is in some way produced by electricity in motion; now it occurred to Mr. Faraday, in consequence of certain phenomena which he observed, and which he has described under the terms *volta-electric*, and *magneto-electric induction*, that magnetism in motion ought to produce an electric current, and he succeeded in verifying this important conclusion as follows: a long spiral coil of copper-wire, covered as in the former experiments with silk, was connected by its extremities with the galvanometer, the deflection of which would of course announce a current of electricity in the spiral and wires connected with it: he now found, that in the act of introducing the pole of a powerful bar-magnet within the coils of the spiral, a deflection of the galvanometer took place in one direction, and in the act of withdrawing it took place in the opposite direction; so that each time the conducting-wire cut the magnetic curves, a current of electricity was, for the moment, produced in it. He afterwards devised the following curious modification of this experiment: c (fig. 206) is a copper plate so mounted as to admit of revolving upon

its axis; *n s* are the poles of a powerful horse-shoe magnet, so placed as to admit of the revolution of the circumference of the plate between them; *w w'* are conducting wires, one of which is retained in perfect metallic contact with the axis, and the other with the circumference of the plate at the point between the poles *n s*. These wires terminate in the galva-

* Any extended details upon this extremely curious subject would be misplaced in a *Manual of Chemistry*: I must, therefore, refer for them to Mr. Faraday's first series of experimental researches in electricity, read before the Royal Society, on the 24th of November, 1831, and published in the *Phil. Trans.* for 1832, p. 125.

nometer g. When the copper plate is made to revolve from right to left, a current of electricity is produced, in the direction of the arrows, and deflects the galvanometer accordingly. If the revolutions of the plate, or the poles of the magnet be reversed, the electric current moves in the opposite direction*.

Mr. Faraday not only succeeded in obtaining galvanometrical indications of an electric current, but, by another modification of the arrangement in which the electric current was induced by an electro-magnet, he actually succeeded in obtaining the electric spark. (*Phil. Trans.*, 1832, p. 132.) The electric spark was afterwards obtained from a common magnet, by Nobili and Antinori, and in this country by Professor Forbes. (*Phil. Trans. Edinb.*, 1832.) For this purpose, a helix of copper wire was formed round the middle of the soft iron holder of a powerful horse-shoe magnet; on making and breaking the contact between the holder and the magnet, magnetism was alternately created and destroyed within it; at these periods of transition, electric currents were induced in the helix, and on so arranging the conducting-wires as at these moments to make and break contact with mercury, a brilliant spark was observed at each motion of the holder. By making the poles of a powerful horse-shoe magnet revolve rapidly before a soft iron armature supplied as in the former case with a helix, or what is still better, causing the armature and helix to revolve before the poles, an electric current is obtained, which not only gives continuous sparks, but ignites wire, decomposes water, and produces powerful shocks. These *magneto-electric machines* whilst they furnish a beautiful illustration of the production of electricity by moving magnetism, seem also to promise some advantage in the medical applications of electricity, and have been elegantly applied to the purpose of obtaining instantaneous light, by causing the spark to inflame the wick of a small spirit-lamp.

The best form of the magneto-electric machine is that contrived by Mr. Saxton, which has been figured and described by Mr. Daniell, (*Introduction*, § 834,) as follows:—

“A very powerful horse-shoe magnet, formed of numerous steel plates closely applied together, or an electro-magnet of soft iron of the same form, is placed in a horizontal position. An armature or bar of the purest soft iron has each of its ends bent at a right angle, and is mounted in such a way that the surfaces of those ends are directly opposed, and close to the poles of the magnet; in this position it may be made to rotate rapidly in a vertical direction, by means of multiplying wheels and an endless band. Two series of copper-wires, covered with silk, are wound round either end of this bar, as compound helices. The extremities of these wires having the same direction, are connected together, and with a small circular disc

* In the year 1824, M. Arago discovered that a magnet suspended over, and parallel to the surfaces of a horizontal rotating copper plate, acquired a tendency to revolve in the same direction with the plate; and also that a rotatory magnet tended to give a similar rotatory motion to a contiguous disc of copper.

—(*Phil. Trans.*, 1825, p. 467.) These phenomena are explained by the electric currents induced in the copper plate by its rotation within the magnetic curves, which currents flow at right angles to the direction of the motion. (FARADAY, *Phil. Trans.*, 1832, p. 146.)

rotating with the armature in a cup of mercury, with which it is therefore in metallic communication in every position of the disc. The other extremities of the wires are united together, and passing without metallic contact through the spindle upon which the apparatus turns, terminate in a small slip of copper with two opposite points placed at right angles to the axis. These, in the act of rotation, alternately dip into, and rise above, the mercury in another cup, which may be connected with the first at pleasure by means of a copper wire. By the laws of magnetic induction, the armature becomes a temporary magnet whenever its bent ends are opposite the poles of the magnet, and ceases to be magnetic when they are at right angles to them. The momentary generation and destruction of the magnetic force, which will be oppositely directed in the bar as its opposite ends become opposed to the same poles in the act of rotation, must, by the laws of magneto-electric induction, induce corresponding opposite electric currents in the copper wire if the circuit be complete, by the immersion of the points at the moment of their passage. The points are so arranged, that, standing nearly at right angles to the revolving bar, they just rise from the mercury as its ends become opposed to the poles of the magnet, and the circuit being thus suddenly broken at the moment of the electric wave, the current passes in the form of a brilliant spark.

"This figure represents a section of Mr. Saxton's magneto-electrical machine. *A B* is the horse-shoe magnet. *C D* the armature of soft iron, standing in a transverse direction to the poles of the magnet. *E F* is the spindle upon which it revolves by means of the multiplying wheels, *E G*. *h i* are the metallic wheel and points by which connexion is made and broken between the mercury cup, *K*, and the ends of the coils of wire round the armature, *C D*.

"By means of this magneto-electrical machine, all the well-known effects of voltaic currents may be very commodiously produced. When

the communication is made between the spindle and the revolving disc by means of a fine platinum wire instead of the dipping points, the wire may be maintained at a red heat; although the effect being produced by alternating currents in opposite directions, a kind of pulsation, or intermission of the light, may be discerned. Upon making the communication between the two mercury cups by means of copper cylinders grasped in the hands, a continued painful contraction of the muscles of the arms takes place, which destroys voluntary motion, and, under certain circumstances, is perfectly intolerable. If the currents be transmitted into liquid electrolytes by means of platinum electrodes, they are readily decomposed; but in consequence of the alternate reversal of their direction, the *anions* and *cations* are mixed together. This, however, may be avoided, by turning up one of the points of the axis, when one of the currents will be cut off, and half the power destroyed, but the usual results of polar decomposition will be obtained. The amount of decomposition in this, as in all other cases, is in proportion to the quantity of electricity which circulates. By means of an electro-magnet and a constant battery, which was capable of decomposing water by the primary current at the rate of eleven cubic inches of the mixed gases per minute, four cubic inches have been obtained in the same time by this secondary force."

From the manner in which a magnet in motion induces an electric current, it was presumed that the earth's magnetism might be rendered subservient to the same purpose, and Mr. Faraday found that a soft iron cylinder, introduced into the helix, as above described, and placed in the direction of the dipping needle, occasioned a deviation in the galvanometer; he even found that in a wire, or helix, moved at right angles to the dipping needle, so as to cut the magnetic curves of the earth, an electric current, sensible to the galvanometer, was induced; and that the rotation of a copper globe, or of a plate placed at right angles to the dip, produced the same effect; hence he concludes that the conducting matters of the earth's crust may be similarly affected by its diurnal revolutions, so as to induce electric currents flowing towards the poles, and suggests the possibility of the production of the Aurora, by returning electric currents from the poles into the atmosphere.

I must here bring to a conclusion this brief outline of electricity, and of the extraordinary phenomena arising out of it, such as the attractions and repulsions of masses of matter, chemical affinity, heat, light, and magnetism: how these attributes of matter are connected, or what is the true nature of their mutual dependence, are questions for future decision, when probably the whole subject will be simplified by referring them to one ultimate cause, in which it is not improbable that even gravitation may itself be included. From what has already been attained in this branch of science, some anticipations may be fairly formed of its probable progress hereafter; and if, among these, we admit the possibility of a more unlimited command than we at present possess over the production or extrication of this extraordinary agent, our speculations would assume a very extensive and interesting aspect; its mechanical and chemical powers would be perpetually called into action; the former as a substitute for steam, wind, and water; and the latter for the more sluggish or circuitous and difficult methods of ordinary decomposition; its

single application to the evolution of oxygen and hydrogen from water, would alone work wonders; and even as a direct source of heat and light, its applications and uses would be gigantic and endless; whilst the facility of its conveyance and transmission, its ubiquity, and its varied attributes in those different states which we, for want of more explicit knowledge of their cause, have termed *quantity* and *tension*, seem to point it out as of unlimited application to human uses.

CHAPTER V.

OF SIMPLE SUBSTANCES.

UNDER the term *simple* or *elementary* substances, we include all those bodies which have hitherto resisted decomposition, or resolution into simpler forms of matter; and although it may be presumed that some, or perhaps many of them, are in reality compounds, and that they will be proved to be so, as science advances, and our means of investigation are extended and improved, yet in the present state of our knowledge, in which experiment and not hypothesis is resorted to as the ultimate test, these substances, numerous and varied as they are, have afforded no satisfactory indications of their compound nature, and must, therefore, be considered not as undecomposable but as *undecomposed*. These substances, amounting to fifty-five in number, are alphabetically enumerated in the following table, and their *equivalents* and the abbreviations, or *symbols* by which they are represented in this work, are annexed.

SIMPLE SUBSTANCES.

	Equiv.	Symbol.		Equiv.	Symbol.
1. Aluminium . . .	26	<i>al.</i>	29. Mercury . . .	200	<i>hg.</i>
2. Antimony . . .	65	<i>anst Sb</i>	30. Molybdenum . . .	48	<i>mol.</i>

The preceding list admits of an easy, obvious, and useful division, into *substances which are, and which are not metallic*, and there are general analogies among the *metals* which enable us to subdivide them into classes; but with respect to the *non-metallic* bodies, the subdivision is more difficult, and the principles of classification usually applied to them are, in many respects, objectionable. If their arrangement be founded either upon their general electrical or chemical relations, as, for instance, into *electro-negative* and *electro-positive* bodies (anions and cations), or into *supporters of combustion* and *combustibles*, or into *acidifying* and *acidifiable* substances, difficulties occur in the details, which are of great practical inconvenience; for the electrical arrangement brings together substances extremely dissimilar in their chemical characters, such, for instance, as oxygen and sulphur, both of which are electro-negative bodies, or *anions*; and the chemical arrangement leads us at one time to class oxygen with sulphur, both being supporters of combustion; and at another to separate them, in consequence of oxygen being eminently a supporter of combustion, and sulphur as eminently a combustible. Again, in regard to the terms *acidifying* and *acidifiable*; oxygen and chlorine are included among the former, and hydrogen and sulphur among the latter; yet oxygen and chlorine combine with each other to form acids, and neither of them being, in any sense of the term, *combustible*, it is difficult to say which is the acidifying and which the acidifiable element: the compound of hydrogen and sulphur is also acid, yet both hydrogen and sulphur are *combustible*, and hydrogen is *acidifiable* in respect to chlorine, as sulphur is in respect to oxygen. In all these arrangements, too, nitrogen stands out (regarding it as elementary), as an obstinate exception; it is *acidifiable* by oxygen, but it is *alkalifiable* by hydrogen; it is neither *combustible*, nor is it in any case a *supporter of combustion*; and its electro-chemical relations are doubtful: indeed the distinction between some of these bodies and the *metals* is not in all cases very definite: there are strong analogies between arsenic, and selenium, and sulphur, so that Berzelius actually arranges selenium with the metals; and some forms of carbon approach so closely in their characters to those of a metal, that Döbereiner speaks of *carbonium* as a metal. Under all these difficulties, many writers have rejected the electrical and chemical analogies of the unmetallic elements as the basis of their classification, and have arranged them, in reference to their supposed importance as chemical agents, and to convenience of discussion: Berzelius divides them, generally, into *oxygen*, which he places by itself as a supporter of combustion, and into *inflammable substances*, in which he includes all the other elements; and then, adverting particularly to the *unmetallic* substances, he subdivides them into three classes, namely,—1. *Permanently elastic or gaseous bodies* (*Gazolyta*): oxygen, hydrogen, nitrogen. 2ndly. *Metalloids*: sulphur, phosphorus, carbon, boron, and silicon. 3rdly. *Salifying substances*, (*Halogenia*): chlorine, fluorine, iodine, bromine. Almost all agree in placing *oxygen* at the head of the list; but scarcely any systematic writers concur in the order in which they describe the remaining unmetallic elements; except, indeed, that they usually place *hydrogen* after oxygen. But the most important difference amongst them is, in what relates to the *compound substances*, some describing them along with, or immediately

after, their respective elements: and others giving the abstract history of each element separately, and then referring to their mutual combinations. It would be useless to point out in detail the objections which may be made to each systematic arrangement, for, after all, that will be preferable which is best calculated to guide and assist the student in the acquisition of the leading facts and doctrines of the science, and which is, at the same time, most convenient for reference. Under these circumstances I have retained, with such modifications as the progress of chemistry has rendered necessary, the general plan adopted in the former editions of this work. Oxygen, and the bodies associated with it in many of their electrical and chemical habitudes, stand first on the list (the *Halogenia* of Berzelius); and these are succeeded by the inflammable and acidifiable bases; but I have not thought it advisable, for reasons just mentioned, to divide them, as formerly, into two classes: they will be described, therefore, in the following order:

1. OXYGEN.
2. CHLORINE, and its combinations with oxygen.
3. IODINE, and its combinations with oxygen and chlorine.
4. BROMINE, and its combinations with the three preceding substances.
5. FLUORINE, and its combinations with the four preceding substances.
6. HYDROGEN, and its combinations with the five preceding substances.
7. NITROGEN, and its combinations with the six preceding substances.
8. SULPHUR, and its combinations with the seven preceding substances.
9. SELENIUM, and its combinations with the eight preceding substances.
10. PHOSPHORUS, and its combinations with the nine preceding substances.
11. CARBON, and its combinations with the ten preceding substances.
12. BORON, and its combinations with the eleven preceding substances.

Arranging these substances according to their analogies, as pointed out by Berzelius, they would stand as follows, but such arrangement, if here adopted, would, I think, be less convenient in its details than that which I have proposed.

GAZOLYTES.

Oxygen.
Hydrogen.
Nitrogen.

HALOGENS.

Chlorine.
Iodine.
Bromine.
Fluorine.

METALLOIDS.

Sulphur.
Selenium.
Phosphorus.
Carbon.
Boron.
Silicon*.

I have not here separately enumerated the *compounds*, as they will be found in the *table of contents*, by reference to which it will also be seen that the same general plan is adopted in respect to the *metals*, the principle on which they are classified being stated in the preliminary observations on their general properties.

The origin of the *names* by which the simple substances are distinguished, will be found under their individual history, but it will be neces-

* I have retained *Silicon*, or *Silicium*, among the *metals* for the convenience which such arrangement affords in describing some of its most important compounds, such as glass, artificial gems, and coloured glasses, in which the metals and their oxides are so essentially concerned.

sary here to advert to the general principles of *nomenclature* applied to their mutual combinations.

All the combinations of oxygen, chlorine, iodine, bromine, and fluorine, with the inflammables and the metals which are *not acid*, are called *oxides, chlorides, iodides, bromides, and fluorides*: the combinations of the inflammable substances with each other, and with the metals, are distinguished by the termination *uret*, as *sulphuret, phosphuret, &c.*, and in some cases the combinations of certain metals with each other are similarly designated: thus we speak of *arseniurets, tellurets, and antimoniuurets*.

The different *proportions* of oxygen in the oxides are distinguished by a prefix derived from the Latin or Greek numerals; thus we have *protoxide, deutoxide* or *binoxide, tritoxide* or *teroxide*, for the first, second, and third stages of oxidizement; and the highest degree of oxidizement is termed *peroxide*; when the proportions of oxygen in an oxide are as 1 to $1\frac{1}{2}$, or intermediate between the protoxide and deutoxide, the compound is termed a *sesqui-oxide*. If the oxide is so constituted as to contain 2 atoms of base, and 1 of oxygen, it is then termed a *suboxide*, or, more definitely, a *dioxide*. The same distinctive nomenclature is applied to the chlorides, iodides, sulphurets, phosphurets, &c.

The names of the *acid* compounds of oxygen are derived from their bases, and where there is only *one*, it is usually designated by the termination *ic*, as *Carbonic acid, Boric acid, Cyanic acid, &c.*; where there are *two* acids of the same base and oxygen, that containing the smallest proportion of oxygen is distinguished by the termination *ous*, and that containing the larger proportion by the termination *ic*; as *arsenious* and *arsenic acid*: where there are *more than two* acid compounds of the same base, more complicated terms are requisite, of which the nomenclature of the acids of sulphur forms a good example; these are *four* in number, and are termed—1. *hyposulphurous acid*; 2. *sulphurous acid*; 3. *hyposulphuric acid*; 4. *sulphuric acid*; and occasionally the acid containing the *maximum* of oxygen is further distinguished by the prefix *per* or *oxy*: thus we sometimes use the terms *oxychloric acid, permanganic acid, &c.* The *saline* combinations of the acids ending in *ous* are distinguished by the termination *ite*, and of those ending in *ic*, by the termination *ate*: thus we have a *hyposulphite*, a *sulphite*, a *hyposulphate*, and a *sulphate* of potassa, &c., and where the acid and base unite in more than one proportion, a distinction similar to that applied to the oxides is resorted to; thus the compound of one atom of potassa and *two* of sulphuric acid is a *bisulphate* of potassa: that of *two* atoms of oxide of lead and one of nitric acid, a *dinitrate* of lead: these are also sometimes called *supersulphate* of potassa, and *subnitrate* of lead; but the preceding terms are more definite. Lastly, the same acid occasionally forms distinct compounds with the protoxide and peroxide of the same metal, forming *protosalts* and *persalts*. Thus we have a *protosulphate* and a *persulphate* of iron, &c. Other more complex cases of nomenclature occasionally arise out of the preceding, which, however, will be sufficiently intelligible when they occur, by reference to the context.

CHEMICAL SYMBOLS.—It may now be necessary to say a few words respecting the *symbols* contained in the preceding table, and the *formulae* in which they will occasionally be used. It is obvious that they repre-

sent the *equivalents* or *atoms* of the elements; thus $n+o$ signifies 1 equivalent or atom of nitrogen = 14, and 1 of oxygen = 8, the sign + implying *combination*; or they may be written either in brackets, thus $(n+o)$, or a line is drawn over them, thus, $\overline{n+o}$. The *number* attached to either symbol indicates the number of atoms of either element in the compound; nitric acid, for instance, is a compound of 1 atom of nitrogen, and 5 atoms of oxygen, and is, therefore, thus written $(n+5o)$. Potassa is a compound of single atoms of potassium and oxygen, and is therefore simply represented by $(po+o)$. Sulphuric acid consists of 1 atom of sulphur = 16 in combination with 3 atoms of oxygen $(8 \times 3) = 24$, and is represented by $(s+3o)$. Sulphate of potassa is composed of 1 atom of potassa = 48, and 1 atom of sulphuric acid = 40, and would therefore be written in symbols thus $\overline{(po+o)+(s+3o)}$. In this case the *proximate* elements of the salt are sufficiently distinguished: but if the object were to express merely its *ultimate* elements these would be written $po+s+4o$. A number on the outside of the bracket indicates the number of the atoms or equivalents of the compound within it: thus, bisulphate of potassa, composed of 1 equivalent of potassa and 2 of sulphuric acid, is represented by $(po+o)+^2(s+3o)$. In regard to water, the salifiable oxides, and the acids, it is often convenient to have symbols representing the *compound*, without reference to its elements, and I shall accordingly, for this purpose, represent the alkalis and salifiable protoxides by capital initials; the common acids by an acute accent over the initial of the base; the peracids by two acute accents; and the subacids by a grave accent; the latter with the addition of a line underneath may indicate the hypoacids. Water may be represented by the letter *q*, from *aqua*. The following table shows a few of the applications of these *abbreviations*, or compound symbols, as opposed to the more circuitous instances of elementary symbols.

	Atomic Symbol.	Abbreviation.
Water	$(h+o)$	<i>q</i>
Potassa	$(po+o)$	P
Soda	$(so+o)$	S
Baryta	$(ba+o)$	B
Oxide of Lead	$(pl+o)$	PL
Hyposulphurous Acid	$(2s+2o)$	$\underset{\sim}{s}$
Sulphurous Acid	$(s+2o)$	\bar{s}
Hyposulphuric Acid	$(2s+5o)$	$\underset{\sim}{s}'$
Sulphuric Acid	$(s+3o)$	\bar{s}'
Sulphate of Potassa	$\overline{(s+3o)+(po+o)}$	$(s'+P)$
Hydrated Potassa	$\overline{(po+o)+(h+o)}$	$(P+q)$
Nitrate of Lead	$\overline{(n+5o)+(pl+o)}$	$(n'+PL)$
Carbonate of Ammonia	$\overline{(car+2o)+(n+3h)}$	$(car'+A)$

In these and the preceding symbols, I have availed myself, with some slight changes, of the principles suggested by Mr. Whewell,

(*Journal of Royal Institution*, I., 437). The symbols of the *elementary substances*, used by Berzelius, differ but little from those which I have adopted, and I have followed him in employing the initial letters of their ordinary Latin names: with this difference only, that he represents potassium, sodium, and antimony, by the initials K. Na. and Sb. (kalium, natrium, and stibium), instead of *po*, *so*, and *an*. In other respects, however, I have found it necessary to introduce some deviations, or rather to reject parts of his method. Berzelius indicates the *atoms* of oxygen by dots placed over the symbol; thus, instead of writing $(n + 50)$ for *nitric*

acid, he uses the abbreviation $\overset{\cdot\cdot\cdot}{\text{N}}$. In like manner he denotes the compounds of *sulphur* by commas; thus, *sulphuretted hydrogen* ($s + h$) he

writes $\overset{2}{\text{H}}$; and where he wishes to represent *two* equivalents of an element, they are denoted by a *dash through* or *under* its symbol; thus $\overset{\text{H}}{\text{H}}$ or $\underset{\text{H}}{\text{H}}$, indicates 2 atoms of hydrogen. The *vegetable* and *animal acids* he abbreviates by using the first letter of their name with a dash *over* it, thus $\overset{\text{T}}{\text{C}}$ $\overset{\text{T}}{\text{C}}$ $\overset{\text{T}}{\text{F}}$ are the *tartaric*, *citric*, and *formic acids*. He also often omits the sign +, and writes the combined elements side by side, the sign of

addition being understood: thus he writes nitrate of baryta, $\text{Ba } \overset{\cdot\cdot\cdot}{\text{N}}$

instead of $\text{Ba} + \overset{\cdot\cdot\cdot}{\text{N}}$. Lastly, he denotes two or more equivalents of one constituent of a compound, by numbers placed in the same position as the indices of powers in Algebra; thus $\text{N } \overset{\cdot\cdot\cdot}{\text{H}}^3$ is the same as $(n + 3h)$. My chief reason for modifying these abbreviations in the way which I have above proposed, is to avoid the obscurity in which they are frequently involved, and the facility with which they become perplexed by imperfect printing, or errors of the press. It must, however, be confessed that in many cases, the representation of the atoms of oxygen by dots above the basic symbol is convenient.

It may perhaps be objected to the abbreviated symbols which I have suggested that they do not carry with them explicit indications of atomic composition: that *nitric acid* for instance is more completely represented

by $\overset{\cdot\cdot\cdot}{\text{N}}$ than by n' , and phosphoric acid by $\overset{\cdot\cdot\cdot}{\text{P}}$ than by p' , but this can only affect the casual reader, and for such, the system of symbols is scarcely profitable in any form.

The great use of symbols is visibly as it were to present the elements of compounds, so that all their possible combinations may be traced with comparative facility, and their less obvious relations detected. They also facilitate the complex computations required in reference to the atomic constitution of various organic compounds, and often enable the teacher to present the student, at one view, with details which, in the ordinary mode of proceeding, would be verbose and complex. Thus the conversion by heat of 1 atom of nitrate of ammonia into 2 of protoxide of nitrogen, and 3 of water, is thus concisely represented:

Nitric Acid.	Ammonia.	Nitrous protoxide.	Water.
--------------	----------	--------------------	--------

$(n + 50) + (n + 3h)$ produce $2(n + 0)$ and $3(h + 0)$: or, taking the ultimate elements of nitrate of ammonia as $2n + 50 + 3h$, they form $2(n + 0) + 3q$: and of such applications many instances will afterwards occur.

PNEUMATIC APPARATUS.—Of the simple substances which we are about to examine, four are known to us in the gaseous state, and amongst their combinations there are many which also assume that form; so that it will be necessary before we enter upon their history, to say a few words respecting the apparatus by which gaseous bodies are procured and examined. The *hydro-pneumatic apparatus* consists of a japanned iron or copper vessel, of different shape and size according to the particular purposes for which it is intended, and containing a shelf perforated with holes through which the gas may pass into inverted vessels properly placed for its reception.

208

In this wood cut, A is the water-trough; B B, inverted glasses for the reception of gas; C, a wrought-iron tube, placed in a pan of charcoal, for the evolution of gases requiring a red heat; D, a retort heated by the spirit lamp E.

269

For experiments, in which *large vessels* are employed for collecting or transferring gases, the annexed form of the apparatus (fig. 209) is most convenient: the trough is placed in a wooden frame or stand *a*; it has a deep part at *b*, and a shallow shelf, upon which the inverted jar may be placed over a groove, as at *c*.

Vessels of various forms are employed for receiving, retaining, and measuring gases. Where it is intended to introduce different substances into the gas, they may be of

the form represented in figure 209, drawn into a neck with a glass-stopper at top, and open at bottom. Some of these should be graduated into cubic inches, and supplied with a stop-cock, as in figure 211. For measuring small quantities of gases, tubes are employed, some of which

should be divided into 100 equal parts, others into tenths and hundredths of a cubical inch, as in figures 212 and 213.

Where large quantities of gases are required to be collected and preserved, we employ *gasholders* and *gasometers*. The annexed cut (fig. 214) represents Mr. Pepys's improved gasholder, made of japanned iron, or what is preferable, of copper. It consists of a body or reservoir *a*, which may hold from two to six or eight gallons:

b, is a cistern from which issue two tubes, supplied with stop-cocks, one entering the reservoir at its upper part, the other continued, as shown by the dotted lines, to near the bottom: *c*, is a short tube issuing from the bottom of the reservoir, and capable of being accurately closed by a screw. *d*, is a glass tube communicating at both ends with the body of the gasholder. When it is intended to fill this apparatus with gas, the tube *c* is closed, and the stop-cocks, *e*, *f*, are opened; water is then poured into the cistern, which, running down the long tube *e*, forces the air out through the shorter one *f*. The reservoir being thus filled, the stop-cocks are closed, and the aperture *c* is opened, into which

the beak of the retort, or tube, whence the gas issues, is introduced, and, bubbling up, displaces the water which runs out at the same opening. When it is seen in the tube, *d*, that nearly the whole of the water is displaced, the aperture *c* is closed; the vessel is now filled with gas, which may either be drawn off into receivers, placed in the cistern *b*, by opening the two stop-cocks *e*, *f*; or by closing the stop-cock *f*, and opening *g*, it may be propelled into bladders, or transferred in any convenient way by an attached tube.

A view and section of the *gasometer* are shown in the following sketches (figs. 215, 216): it may be made of japanned iron or copper. *a a*, is the outer circular vessel, or pail, to the sides of which the tubes *d*, *e*, (each fitted with a stop-cock externally,) are soldered. The tube *d* passes along the

bottom of the pail, and proceeds to the centre, where it joins the tube *e*, which commences at the top of the pail at the cock *e*, and proceeds downwards; and, from the place of junction, the upright tube *g* rises through the middle of the pail, a little above the level of its upper rim. The vessel *b* is a cylinder open only at the bottom, and of less diameter than the pail in which it is inverted, and can move up and down freely. This cylinder has a solid stem *c*, which passes through a hole in the cross-bar of the frame fixed to the top of the pail; it serves to steady the cylinder, and to indicate the quantity of the enclosed gas; the weight of the cylinder is counterpoised in any convenient way; generally by a weight and chord passing over the pulley *f*.

To use this gasometer, first let the cylinder fall to the bottom of the pail, and fill the latter with water; then shut the cock *e*, and open *d*, and connect with it the tube which conveys the gas from the retort, gasholder, or other vessel; or, if more convenient, shut *d*, and convey the gas through *e*. The gas rises, and gradually lifts up the cylinder, which must be properly balanced: and when sufficiently filled, the cock, by which it entered, must be closed. The gas may now be drawn off at either of the stop-cocks, by a tube passing into the water-trough, or it may be propelled through a blow-pipe, or otherwise employed.

Those gases which are absorbed by water, may, in most instances, be collected over mercury. The best form of the *Mercurio-pneumatic apparatus* is that contrived by Newman (*Quarterly Journal*, vol. i., p. 185). It is a trough of cast-iron, supported by brass or iron legs, and having a small gasometer at one end. It is placed in a japanned iron tray to collect the scattered mercury, as shown in the wood-cut (fig. 217).

a is the shallow, *b* the deeper part, of the trough; *c* is a small mercurial gasometer connected with it, filled from the bottom through the small basin of mercury at *d*; *e* is a sliding stand for a lamp, *f* a detonating tube, screwed into a spring support. It frequently happens that a mercurial pneumatic trough, upon a much smaller scale than the above, is sufficient for mere experiments of research; and, in that case, it is either made of cast-iron or of wood, being hollowed out of a block of mahogany. The chemical lecturer may in many instances altogether dispense with the trouble and expense of a mercurial-bath, by availing himself of the method of collecting gases in dry glass vessels, as described at page 366; especially when he requires very large jars or bottles to be filled with gas, and at the same time kept *dry*, but where a small admixture of atmospheric air is unimportant.

§ I. OXYGEN.

THIS elementary body was discovered by Priestley on the 1st of August, 1774; he called it *dephlogisticated air*; it was termed *empyreal air* by Scheele, and *vital air* by Condorcet. The name *oxygen*, was given to it by the French nomenclaturists, implying its tendency to form *acid* compounds (from $\acute{o}\xi\upsilon\varsigma$, *acid*, and $\gammaεννέιν$, *to generate*). It is more abundantly diffused throughout nature than any of the other elementary bodies; it forms eight-ninths of the weight of water, about one-fifth of the weight of the atmosphere, and a large relative proportion of the mineral bodies which form the solid matter of the globe. It also forms, with scarcely one exception, an element of the various products of organized bodies both animal and vegetable.

Oxygen gas may be procured by a variety of processes, of which those only in common use will be noticed here, and others adverted to in their proper places.

To obtain oxygen in the purest state, proceed as follows: introduce into a small glass *retort* (as shown at D, fig. 208,) about 100 grains of the salt called *chlorate of potassa*, and gradually heat it over a gentle charcoal fire, or by means of a large spirit-lamp, having previously placed the beak of the retort under the shelf of the hydro-pneumatic apparatus. Suffer the common air of the retort to escape, and when the salt fuses and appears to boil, collect the oxygen which it then gives out in proper vessels, taking care so to adjust the heat as to cause the gradual decomposition of the salt, and occasion the air-bubbles to follow each other with moderate rapidity, especially towards the end of the process, when a torrent of gas is apt to be rather suddenly evolved, in consequence of the formation of a portion of perchlorate of potassa, which is decomposed at that period. At last, the heat may be so far increased as to render the bottom of the retort red-hot, being careful, however, not to fuse it; when gas ceases to be evolved, withdraw the retort and put it aside: it is seldom fit for a second operation. From 100 grains of the chlorate, we may expect to obtain nearly 100 cubic inches of gas.

Another substance from which oxygen may be obtained, at a cheaper rate, is *black oxide of manganese*, but the gas is not perfectly pure, and the quantity produced from a given weight of the oxide is very variable. A pound should yield from 40 to 50 pint measures. (11 ounces troy, will give 1 ounce, or 1387 cubic inches. —THOMSON. 1 ounce yields, if quite pure, 128 cubic inches. —TURNER.) The oxide of manganese should be powdered, dried, and introduced into an iron gas bottle, which may be about four-fifths filled with it, and placed with its proper connecting tubes, in a convenient furnace or fire-place. These bottles should be made of wrought-iron, of the shape annexed (fig. 218), their capacity being from one to three pints. The connecting tube *a* should

be of iron, and fitted by grinding into the neck of the bottle; and the delivery tube *b*, which may be of pewter, with a brass or copper piece soldered on to it at its conical end *c*, should be similarly ground into the upper end of the connector. When these bottles are used, the joints may be made tight by the previous application of a little grease.

When the oxide of manganese becomes red-hot, the oxygen begins to escape by the pewter tube, which must be so bent as to pass under the shelf of the water apparatus. Collect some of the gas in a small jar or tube, and test it by introducing into it a slip of wood which has been inflamed and blown out, so that the end remains only glowing; if the gas be sufficiently pure, it will immediately burst into flame and burn vehemently: the oxygen may then be collected for use, either in bottles, jars, gasholders, or gasometers, as required. When the gas ceases to be evolved, the bottle must be removed from the fire; and, when cold, emptied of its contents, which will be found to be an oxide of manganese, of a brown colour, containing of course less oxygen than the black, and not further decomposable by heat alone.

Oxygen gas may also be obtained from a mixture of pulverised black oxide of manganese and sulphuric acid, in such proportions as to be about the thickness of cream; this mixture is put into a glass retort, and heated over an Argand lamp, the gas being collected in the usual way. This method is sometimes convenient where an iron retort cannot be procured; but it is not economical, and the ingredients are apt to harden in the retort, which is often broken in attempting to cleanse it.

If perfectly pure oxygen be required, it must not only be obtained from chlorate of potassa, but also collected over mercury; and as it is often wanted in the experimental laboratory in very small quantities only, a tube-retort, made of green or plate-glass, bent into the annexed form (fig. 219), may be conveniently used.

It must also be recollected, in all delicate experiments with oxygen and other gases, that they retain, as usually procured, more or less vapour of water, so that to obtain them *dry*, it is necessary to convey them through tubes over substances which will abstract the watery vapour which they contain, without in any way affecting the purity of the gas itself. Oxygen may thus be dried by passing it through a long tube containing fragments of fused *chloride of calcium*: sulphuric acid, fused potassa, and some other substances, are occasionally used for the same purpose.

Oxygen gas is insipid, colourless, and inodorous; it is permanently elastic, under all known pressures and temperatures. Its specific gravity, compared with air, is as 1.111 to 1.000. Compared with hydrogen, its specific gravity is = 16, hydrogen being = 1. At mean temperature and pressure, 100 cubic inches weigh 34.60 grains: or according to Thomson, 36.43 grains at the temperature of 32°. According to Dulong and Berzelius, the specific gravity of oxygen is 1.1026, and 100 cubic inches weigh 34.109 grains (*Ann. de Chim. et Phys.*, xv., 386); according to Davy, its specific gravity is 1.127. Its refractive power, in regard to light, is less than that of any known body: compared in this respect with

atmospheric air, it is as 0·830 to 1000. According to De la Roche and Berard, its specific heat, compared with an equal *volume* of air, is = 0·9765, and with an equal *weight* of air, = 0·8848, that of air being = 1·000. It is evolved by electrolytic action at the positive pole or anode, and therefore stands among the anions, as defined by Faraday, (p. 307: and figs. 163 and 164.)

When powerfully compressed by the sudden depression of a piston in a glass tube, oxygen appears to become momentarily luminous, a property which has been considered as one of its characteristics. Thenard, however, has shown that this appearance is connected with the presence of grease or oil upon the compressing piston, and that the gas, although much heated by sudden compression, is not of itself luminous. It is absorbed in very small quantity only by water: 100 cubic inches of water, freed from air, only taking up 3·5 cubic inches of oxygen (HENRY, *Phil. Trans.*, 1804, p. 174). It does not alter the colour of litmus, nor does it render lime-water turbid.

It is a powerful supporter of respiration. A small animal, confined in oxygen gas, lives thrice as long as when confined in the same bulk of common air; it has, therefore, been called *vital air*; but we are not thence to conclude that it is fit for the continuous support of life: on the contrary, an animal made to breathe oxygen for any length of time, falls a sacrifice to excess of arterial action, and after death the blood in the veins is found as florid as that in the arteries.

Oxygen eminently *supports combustion*. A lighted taper, introduced into this gas, is very rapidly consumed, with intense ignition and enlargement of the flame; and if it be previously blown out, so that the wick continues glowing (and for such experiments pieces of *green wax*-taper answer best), it immediately bursts into flame when plunged into the jar of oxygen. Sulphur, which burns in the air with a small blue flame, has its flame enlarged when immersed in a jar of oxygen, and blazes with a beautiful purple colour. It dissolves as it were in the oxygen, and converts it into sulphurous acid gas, which is absorbed by water. Phosphorus, when inflamed in the atmosphere, burns with a bright light, but in oxygen the eye can scarcely bear its brilliancy, and the heat which it evolves is very intense. A piece not larger than a pea should be used in the experiment. The oxygen combines with the phosphorus, and forms a quantity of white flaky matter, very soluble and deliquescent, which is chiefly phosphoric acid. This, and the combustion of sulphur, may be best performed by placing them in a small copper spoon or cup, attached to a wire annexed to a spare stopper, or passing through a cork which fits the neck of the air-jar. The disadvantage of a cork is, that it is sometimes apt itself to take fire and crack the jar.

One of the most brilliant instances of combustion in oxygen is the burning of iron wire. For this purpose the jar should be capacious, and placed over water in a common soup-plate; the oxygen should be very pure. A piece of thickish annealed iron-wire should be attached to the spare stopper, and loosely wound round with repeated twists of harpsichord-wire, so as to form a tangled coil, nearly the thickness of one's finger; the sulphur tip of a match should then be broken off, and affixed to the end of it; when this is inflamed, and the coil immersed into the

jar of gas, vivid combustion soon ensues: it throws off brilliant sparks, and partly fuses into globules of oxide iron, which fall through the water, and lie for some time red-hot upon the plate, which they often fuse at the point of contact. A piece of annealed watch-spring, a thin file, or long shavings which may be obtained from the turners of steel or iron, may also be used for this experiment.

In all these cases of combustion in oxygen gas, the sudden expansions which take place are apt to endanger the bell-glass, which should, therefore, be held by the hand, so as to allow the occasional escape of a little of the gas, and at the same time prevent its jarring upon the plate beneath.

The results of the above, and other cases of combustion in oxygen, will be more fully detailed and explained hereafter.—(See CARBON, SULPHUR, PHOSPHORUS, and IRON.) It may suffice to state at present, that in all cases of combustion in oxygen, the combustible and the oxygen combine, and the product of combustion consequently manifests an increase in weight proportionate to the quantity of oxygen with which it has united. *Acids, alkalis, earths, and oxides*, will be found to be the result of these combinations, which are either effected slowly, and without the evolution of heat and light; or rapidly, with the phenomena of combustion and flame: or with intermediate rapidity, exciting considerable elevation of temperature, and often even a red heat, though without flame, as in some cases which have been already cited (p. 225).

The terms *oxidizement* and *oxidation* imply the combination of oxygen with bodies; and its abstraction or separation is *deoxidizement* or *reduction*. All the elementary substances are susceptible of oxidizement, and most of them, at certain temperatures, with the evolution of heat and light; these are in common language termed *combustible*, or *inflammable bodies*; when a substance is saturated with oxygen, it becomes *incombustible*; that is, incapable of entering into further combination with it. Bodies saturated with the other supporters of combustion are also incombustible, hence the perchlorides, periodides, &c., come usually under that definition. All *organic* bodies are combustible.

The *phenomena of combustion* were referred by Stahl and his associates to a peculiar principle which they called *phlogiston*; it was supposed to exist in all combustibles, and combustion was said to depend upon its separation: but this explanation, though apparently supported by experimental evidence, was at variance with the well-known fact, that bodies during combustion increase in weight.—See *History of Chemistry*, p. 35.

After the discovery of oxygen gas, it was adopted by Lavoisier as the universal supporter of combustion. The basis of the gas was supposed to unite to the combustible, and the heat and light which it before contained in the gaseous state, were said to be evolved in the form of flame. But in this hypothesis several requisites are not fulfilled; the light depends upon the combustible, and not upon the quantity of oxygen consumed; and there are numerous instances of combustion in which oxygen, instead of being solidified, becomes gaseous during the operation, so that the theory of latent heat is insufficient; and, lastly, in others, no oxygen whatever is present. Combustion, therefore, cannot be regarded as dependent upon any peculiar principle or form of matter, but must be considered as a general result of intense chemical action. It may be

connected with the electrical energies of bodies; for all bodies which powerfully act upon each other are in the opposite electrical states of positive and negative; and the evolution of heat and light may depend upon the annihilation of these opposite states, which happens whenever they combine.—See the *Prefatory History of Chemistry*; the Section on *Electricity*; and the article *Atmospheric Air*.

§ II. CHLORINE.

CHLORINE was discovered by Scheele in 1774. Consistently with his theoretical notions of its nature, he called it *dephlogisticated muriatic acid*.—(*Mem. Acad. Stockholm*, 1774, p. 94.) The term *oxymuriatic acid* was afterwards applied to it by the French chemists.—(BERTHOLLET, *Jour. de Phys.*, p. 325.) The more appropriate term *chlorine*, (from *χλωρὸς*, *green*;) which merely designates its greenish-yellow colour, was given to it by Sir H. Davy, who, in 1810, published a masterly essay on its nature, in the *Phil. Trans.*, showing that, so far from containing loosely-combined oxygen, as had been suspected, that element could not be proved to exist as one of its component parts; also that it contained no muriatic acid; that in all cases of the *apparent* evolution of oxygen and muriatic acid from chlorine, water was present, and was decomposed; and that, in the present state of our knowledge, chlorine must be regarded as an uncompounded or elementary body. Its great natural source is sea-salt, or *chloride of sodium*: it also occurs in several other combinations.

To obtain chlorine, a mixture of one part by weight of coarsely-powdered black oxide of manganese and two parts of common hydrochloric acid may be heated over a lamp in a glass retort. Chlorine is soon copiously evolved, and may be conveniently collected over warm water; it is absorbed by cold water, and cannot, therefore, be long retained over that fluid; so that it should be received into bottles provided with ground stoppers: when these are full, the stopper, previously greased a little, should be introduced under water, care being taken to exclude the water from their interiors. In consequence of the deleterious nature of chlorine, its escape into the atmosphere of the laboratory should be prevented, by collecting the first portions which come over mixed with the common air of the retort, in a jar, which may afterwards be carried away into the open air, or placed under a chimney. The gas may be preserved for use when it passes over of its full colour, to judge of which, the neck of the retort should be kept clean; it should not be more than half filled with the materials, which are otherwise apt to boil over, and soil the water in the trough.

When chlorine is required perfectly pure and free from hygrometric moisture, it should be first passed through water, and afterwards conducted through a long tube containing fragments of fused chloride of calcium, and ultimately into a clean dry bottle, from which it will expel the atmospheric air, as explained by fig. 222; it cannot be collected over mercury, as it immediately combines with that metal.

Chlorine may also be procured from a mixture of 8 parts of common salt, 3 of pulverized black oxide of manganese, 4 of water, and 5 of sulphuric acid: or the proportions recommended by Thenard may be used; viz., 4 parts of common salt, 1 part of oxide of manganese, 2 of

sulphuric acid, and 2 of water. The theory of its production in these cases will be explained afterwards.—See *Hydrochloric Acid*, and *Sulphate of Soda*.

Chlorine, at common temperatures and pressures, is a gaseous fluid, which, when perfectly dry, suffers no change by exposure to a temperature much below 0° ; but, in its ordinary state, it generally contains aqueous vapour, which, at a temperature of 32° , is deposited in combination with chlorine in the form of a white crystalline compound, which liquifies, effervesces, and is again taken up by the gas, upon the application of heat. This *hydrate of chlorine* may be best obtained by introducing into a clean bottle of the gas a little water, and keeping it for a few days in a dark place, at a temperature not exceeding 32° . It then forms prismatic and acicular crystals, having a specific gravity of about 1.2 and composed, according to Faraday, of 27.7 chlorine and 72.3 water, or about 1 proportional of chlorine to 10 of water.—(*Quarterly Journal*, xv.) Chlorine was the first of the gases supposed to be permanently elastic which Mr. Faraday succeeded in condensing into the liquid state: he effected this by putting some of the hydrate of chlorine into a small bent tube, hermetically sealed, and applying a gentle heat, a yellow vapour formed, which condensed in the cold part of the tube into two distinct fluids, the uppermost and lightest of which was mere aqueous solution of chlorine, but the heavier was yellow, and separable by careful distillation; it did not solidify at 0° . If, when the fluids were separated, the tube was cut in the middle, the parts flew asunder with an explosion, the whole of the yellow portion disappeared, and gaseous chlorine was produced. When the end of the tube in which the yellow fluid lay was broken under water, there was also an immediate evolution of chlorine gas. The specific gravity of liquid chlorine is about 1.33. It is a non-conductor of electricity; its refractive power is rather less than that of water.—(*Phil. Trans.*, 1823, p. 160.)

Chlorine, when dry and pure is not affected by light, neither is it altered by exposure to very high temperatures. By means of the following apparatus, Sir H. Davy exposed it to the continued action of charcoal intensely ignited by voltaic electricity, without the smallest change in its properties. A glass globe (fig. 220), of about four inches diameter, has at its upper part a sliding wire passing air-tight through a ground collar, to the lower end of which is attached a piece of well-burned charcoal: at bottom is a stop-cock supporting a pincers, in which is another pointed piece of charcoal; the globe is exhausted upon the air-pump, filled with chlorine, and the stop-cock and sliding wire attached to the extremities of the voltaic apparatus; the charcoal points are then brought into contact by pushing down the upper wire, and they are thus retained as long as necessary in intense ignition.

Chlorine gas is of a greenish-yellow colour, a pungent and disagreeable smell, a peculiar and somewhat astringent taste, highly irritating and injurious when respired, and exciting cough and great irritation of the lungs, and mucous secretion from the trachea and bronchiæ, even when

considerably diluted with atmospheric air. In some pulmonary complaints, the respiration of air slightly tainted by the admixture of chlorine has been resorted to as a stimulant. The specific gravity of chlorine compared with air, is, according to Gay Lussac and Thenard, 2·470, which gives 76·59 grains as the weight of 100 cubical inches at mean temperature and pressure. According to Thomson, the specific gravity of chlorine is 2·5, and at the temperature of 32° 100 cubic inches weigh 81·975 grains. According to Davy, 100 cubic inches weigh between 76 and 77 grains. Its specific gravity, in reference to hydrogen, may be considered as 36 to 1, (according to Berzelius 35·42, and according to Turner 35·84. *Elements of Chemistry*, fifth edit., p. 230.) Chlorine is an electrolytic anion.

At the temperature of 60°, water dissolves two volumes of chlorine. The solution has a specific gravity of 1·008; it is of a pale yellow colour, has an astringent, nauseous taste, and destroys vegetable colours: hence its use in bleaching: though the gas itself, when perfectly free from moisture, has scarcely any such action. Hence it is probable that the bleaching agency is due to the evolution of nascent oxygen resulting from the decomposition of water; and there are other compounds containing oxygen, but no chlorine, which are also bleaching agents, such as the peroxide of hydrogen, and manganic and chromic acids. The bleaching power of dew, and sometimes of rain-water, renders it probable that they also contain some excess of oxygen, perhaps in the form of the peroxide of hydrogen.

When aqueous solution of chlorine is exposed to the direct rays of the sun, oxygen is evolved in consequence of the decomposition of the water, the hydrogen of which unites to the chlorine, and forms hydrochloric acid. The same change ensues more slowly in common day-light, but in the dark there is no such decomposition. As gaseous chlorine generally contains aqueous vapour, the bottles in which it is preserved should be excluded from light.

Chlorine, and its aqueous solution, are powerful antiseptics, and destroyers of contagious and infectious matter, and of bad odours. This property depends upon the power which chlorine has of decomposing those noxious compounds, and resolving them into others which are harmless. For the purposes of fumigation, chlorine liberated from black oxide of manganese and hydrochloric acid, or from manganese, salt, and sulphuric acid, may be diffused through the atmosphere of the infected chambers; or the infected goods may be exposed to it. In the same way the offensive odours of dead bodies may be mitigated by sprinkling them with solution of chlorine. (Faraday, *Quar. Jour.*, xviii., p. 92. See Chloride of Soda, Chloride of Lime, &c.)

When a burning taper is immersed in a jar

of chlorine, the brilliancy of the flame is much impaired; it becomes red, throws off dense fumes and is soon extinguished. There are, however, many bodies, such as phosphorus and several of the metals, which are spontaneously ignited by chlorine, and burn in it with much brilliancy. In these cases, binary compounds result, some of which, like those of oxygen, are possessed of acid properties: others are not acid, and are termed *chlorides*. Brass or copper leaf, and powdered antimony, serve well to show the intense action of chlorine upon certain metals. When introduced into the gas, they enter into immediate combustion, and *chloride of copper* and *chloride of antimony* are formed. The most elegant way of making these experiments consists in introducing the phosphorus, or the copper leaf, into a retort (fig. 221), mounted with a stop-cock, and exhausted upon the air-pump; it is then screwed into the cap of an air-jar of chlorine, also mounted with a stop-cock, and standing over water. Upon opening the cocks, the gas rushes into the retort, and the phosphorus or copper leaf immediately burns. In consequence of their irregular thickness and form, retorts are frequently broken by the air's pressure whilst exhausting; so that it is safe to cover them with a cloth during the process, to prevent the splinters being thrown about. A piece of bibulous paper, dipped into oil of turpentine, is also spontaneously inflamed when put into a jar of chlorine.

The presence of chlorine is recognized by its bleaching power, by its odour and colour, and by its action upon solution of nitrate of silver, in which it occasions a white curdy precipitate, insoluble in nitric acid, but soluble in liquid ammonia, and speedily blackening by exposure to light. It is also detected by electrolytic action, as already shown (p. 308).

CHLORINE AND OXYGEN.—No compound of these two elementary substances can be obtained by their direct mutual action, for they have but a feeble affinity for each other, and, when combined, are easily separable. By presenting chlorine and oxygen, however, to each other, under certain conditions, they have been found to form four distinct compounds.

1. PROTOXIDE OF CHLORINE. HYPOCHLOROUS ACID. ($C + O$), or \dot{C} . In the *Phil. Trans.* for 1811, Sir H. Davy has described a peculiar gas, to which, on account of its deep yellow-green colour, he gave the name of *euchlorine*. He obtained it by mixing in a small retort, 2 parts of chlorate of potassa with 1 of water, and 1 of hydrochloric acid, and applying *a very gentle heat*, so as to cause a moderate effervescence: he collected it in small jars or tubes over mercury, but the best way of examining it is to retain it in the tube or vessel in which it is generated, or to collect it in a clean dry phial or jar, as described by fig. 222 at the foot of the next page.

This gas has a peculiar odour, like diluted chlorine, and is pernicious to respiration. Davy found its specific gravity to vary; he estimated it at about 2.4: Gay Lussac and Thenard regard it as = 3. Water dissolves ten volumes of this gas, and acquires its peculiar odour, and a deep yellow colour; it destroys most vegetable colours, previously reddening some of the blues. Its most remarkable character is the facility with which it is decomposed: when gently heated in the upper part of a small tube standing over mercury, a kind of explosion, attended by a flash of light, ensues, and the tube is projected to some distance; but if it be firmly

held down in the mercury, the results of the decomposition are retained. According to Davy, 50 volumes are thus expanded to 60, consisting of a mixture of 40 of chlorine and 20 of oxygen. According to Gay Lussac, 1 volume becomes by decomposition $1\frac{1}{2}$, composed of 1 volume of chlorine and $\frac{1}{2}$ a volume of oxygen. According to this view, *protoxide of chlorine* would consist of

				Gay Lussac.

This gas sometimes explodes whilst it is collecting, or in being transferred from one vessel into another, or even by the heat of the hand, so that it should be cautiously dealt with and examined, and collected in small quantities only*. Detonated with hydrogen, in the proportion of five measures of the gas to eight of hydrogen, it gives rise to the production of water and hydrochloric acid. It is decomposed by all burning bodies, and their combustion continues as it would in a mixture of chlorine and oxygen in the above-mentioned proportions. A small piece of phosphorus let up into the gas instantly takes fire and absorbs it, burning with much brilliancy.

The experiments of Soubeiran (*Ann. de Chim. et Phys.*, xlviii., 113) rendered it probable that euchlorine is not a definite compound, but a mixture of chlorine with the peroxide of chlorine, an opinion which some of Sir H. Davy's observations appear to corroborate; at least he found that water resolved it into chlorine and peroxide of chlorine. Soubeiran

* There are certain gases which are absorbable by water, but which, being either heavier or lighter than atmospheric air, may with a little management be collected sufficiently pure by placing the materials for producing them in a flask, furnished with a tube of convenient length, and twice bent at right angles, so as to pass to the bottom of a clean stoppered phial: the disengaged gas, if heavier than the air, displaces it; when it is full, it must be cautiously withdrawn, and stopped, and another phial put into its place: see the wood-cut (fig. 222) A. If the gas thus to be collected is lighter than the atmosphere, the tube from the flask may be straight, and pass up into an inverted phial, as at B.

passed it over calomel, by which its excess of chlorine was absorbed and peroxide of chlorine was liberated. The nonaction of this gas on copper-leaf seems, however, to justify its being considered definite, although Davy found that a mere *mixture* of peroxide of chlorine with chlorine did not immediately act upon copper leaf.

Such was the extent of our information respecting the nature of this compound of chlorine and oxygen previous to the researches of Balard, who, in an elaborate paper on the nature of the bleaching combinations of chlorine (*Ann. de Chim. et Phys.*, lvii., 225; and Taylor's *Scientific Memoirs*, i., 269) has more fully investigated its properties, and shown the mode of obtaining it in a pure form; he has also proposed to designate it *hypochlorous acid*. His process consists in agitating a mixture of one part of finely-powdered red oxide of mercury with twelve of distilled water, in a bottle filled with chlorine; the gas is rapidly absorbed: if the proportion of the oxide is insufficient the deposited powder is white, and some of the chlorine remains unabsorbed; but the oxide should be in slight excess, so as to remain red, and entirely absorb the gas, (6 drachms of red oxide mixed in fine powder, with an ounce and a half of water, and shaken in a quart bottle of chlorine are the proportions recommended by Mr. Graham.) When the absorption is complete, the contents of the bottle are poured upon a filter, and the filtrated liquor subjected to distillation in vacuo, by which a diluted solution of hypochlorous acid is obtained, and which may be concentrated by a second distillation. After enumerating the properties of this liquid or aqueous acid, M. Balard proceeds to show the mode of obtaining from it the pure gaseous acid: this he effected by throwing up into an inverted jar of mercury a small quantity of the liquid acid, and then passing into it, through the mercury, small fragments of fused nitrate of lime; this salt abstracts the water and liberates the pure *hypochlorous acid* in the state of a gas, a little deeper coloured than chlorine, of a strong penetrating odour, and absorbable by mercury, from the contact of which it is preserved in the above mode of obtaining it, by the layer of solution of nitrate of lime. Water dissolves many times its volume, forming a pale-coloured solution, similar to that originally obtained by distillation in vacuo. A slight elevation of temperature is sufficient to decompose this gas, with explosion and evolution of heat and light, so that it requires careful management. It is not changed by some hours' exposure to diffused daylight, but direct solar rays decompose it in a few minutes without explosion: when mixed with hydrogen and inflamed, it detonates violently, but at common temperatures the mixture remains unchanged. Bromine and iodine slowly decompose it; sulphur, selenium, phosphorus, and arsenic decompose it with sudden and violent detonation; charcoal also causes it to explode, apparently in consequence of the condensation which the gas suffers in its pores. Blotting-paper introduced into the gas also causes its sudden decomposition into a mixture of chlorine and oxygen; indigo decomposes it slowly and with more complicated changes. By the action of oxalic acid it forms carbonic acid, and chlorine is evolved. M. Balard found, by various analytical methods, that the composition of this hypochlorous acid gas is analogous to that of Davy's *euchlorine*; that is, that it consists of 1 volume of chlorine and 0.5 volumes of oxygen, condensed into 1 volume; but he gives reasons which we shall again

advert to in speaking of some of the hypochlorites, for regarding the equivalent of the hypochlorous acid, not as $36 + 8 = 44$, but as $72 + 16 = 88$; that is, as consisting of

Chlorine	..	2	..	72	..	81.82
Oxygen	..	2	..	16	..	18.18
		—		—		—
		1		88		100.00

The aqueous solution of this acid is pale yellow; it has a peculiar penetrating odour, and an acrid but not acid taste; it attacks the cuticle with great energy, destroying it more rapidly than nitric acid, and communicating to it a reddish-brown-colour. It decomposes at common temperatures, and in summer requires to be kept in ice, and in a dark place. In the voltaic circuit it disengages oxygen, but no chlorine at the positive pole: the latter, no doubt, unites to the nascent hydrogen to form hydrochloric acid. It is rapidly decomposed by iron-filings, but of the other metals there are few which have any very energetic action upon it. It is curious that, with the exception of silver, they become oxidized and evolve chlorine; silver, on the contrary, evolves oxygen, and combines with the chlorine. It converts bromine and iodine into bromic and iodic acids; and sulphur, phosphorus, selenium, and arsenic, into their acids, with the evolution of chlorine. When a concentrated solution of this acid is mixed with ammonia, or when a fragment of sulphate or phosphate of ammonia is suspended in it, drops of the *explosive chloride of nitrogen* are formed: if both solutions are concentrated, effervescence and decomposition ensue.

PEROXIDE OF CHLORINE. CHLOROUS ACID. HYPOCHLORIC ACID. ($C + 4O$)

or $\overset{\cdot\cdot\cdot}{C}$, was discovered by Sir H. Davy, in 1815 (*Phil. Trans.*, p. 214). It is obtained as follows:—about 50 grains of chlorate of potassa are moistened with a few drops of concentrated sulphuric acid, and rubbed together with a platinum spatula, till they incorporate and form a solid mass of an orange colour. This mass is to be introduced into a small glass retort, and gradually warmed in a water-bath, the temperature of which must be carefully kept below 212° , which may be managed by mixing alcohol with the water. (Or we may use a small tube, sealed at one end, as a substitute for a retort, and fitted with a cork perforated by a small *S* tube,

223

as in fig. 223, where *a* represents the tube, which should be wrapped round with a little tow, in case of explosion, to prevent fragments being thrown about; *b* the cork, &c.) A bright yellowish-green elastic fluid passes off, which is rapidly absorbed by water, but may be collected in small tubes

over mercury. The colour of this gas is more brilliant than that of the protoxide, and its odour peculiar, and unmixed with the smell of free chlorine. Its specific gravity, compared with air, is, according to Davy, as 2.360 to 1.000; theoretically 2.338; compared with hydrogen it is as 34 to 1, 100 cubic inches therefore should weigh, at mean temperature and pressure, 72.012 grains. When peroxide of chlorine is heated to a temperature somewhat below that of boiling water, it explodes with much violence and the evolution of a bright light. The result of

this decomposition is, that two volumes of the gas are expanded into three, two of which are oxygen, and one chlorine; the relative weights, therefore, of its elements, are 32 of oxygen and 36 of chlorine. It requires the same, and even greater precautions, in preparing and transferring, as the former gas*.

Its saturated aqueous solution (containing about 7 volumes of the gas to 1 of water) is of a deep yellow colour, an astringent and corroding taste, and when applied to the tongue, leaves for a long time a very disagreeable sensation. It destroys vegetable colours. It is absorbed according to Martens (*Ann. C. & P.*, lxi. 293,) by alkaline solutions, forming with them a peculiar class of bleaching salts.

Mr. Faraday condensed this gas by enclosing the mixture of chlorate of potassa and sulphuric acid in a sealed tube, and leaving them to act upon each other for twenty-four hours. In that time there had been much action; the mixture was of a dark reddish-brown, and the atmosphere within of a bright yellow colour. The mixture was then heated up to 100° , and the unoccupied end of the tube cooled to 0° : by degrees, the mixture lost its dark colour, and an ethereal-looking liquid condensed. It was not miscible with a small portion of the sulphuric acid which lay beneath it; but when returned on to the mass of salt and acid, it was gradually absorbed, rendering the mixture of a much deeper colour. "The peroxide of chlorine thus obtained is a very fluid transparent substance of a deep yellow colour. A tube containing a portion of it in the clean end was opened at the opposite extremity; there was a rush of euchlorine vapour, but the salt plugged up the aperture: whilst clearing this away, the whole tube burst with a violent explosion." (*Phil. Trans.*, 1823, p. 194.) Sir H. Davy found that, of the unmetallic combustible substances, phosphorus was the only one which spontaneously decomposed this gas: the phenomena were the same as with the protoxide of chlorine. Two volumes, detonated with five of hydrogen, produce water and hydrochloric acid. When absorbed by solution of potassa, chlorate of potassa and chloride of potassium are formed. According to Davy and Gay Lussac, this gas consists of

CHLORIC ACID ($C + 5O$) or C' , or \dot{C} .—In the compound which has been thus called by its discoverer, M. Gay Lussac (*Annales de Chimie*,

* For the purpose of illustration, in lectures, this gas may be conveniently obtained by putting a few grains of chlorate of potassa into the bottom of a tall narrow tube or jar (half an inch diameter and about twelve high), standing upon a foot, and carefully dropping in upon the salt, so as not to soil the sides of the tube, a little sulphuric acid: the peroxide of chlorine is immediately evolved (provided no explosion ensues), and its

weight causes it to expel the superincumbent air and fill the tube, from which, with a little management, it may be decanted into a tall glass containing copper-leaf, upon which it exerts no action; but a hot wire, dipped into the gas, causes it immediately to explode, and the metal then burns in the mixed oxygen and chlorine. A little jet of nitric oxide thrown in, produces the same effect, without explosion.

tom. xci., p. 108), the relative proportions of chlorine and oxygen are to each other as 36 to 40: chloric acid cannot exist independent of water or some base, and, therefore, its properties in the dry or anhydrous state are not known.

Chloric acid may be prepared by passing a current of chlorine through a mixture of oxide of silver and water. Chloride of silver is produced, which is insoluble, and may be separated by filtration. The excess of chlorine, which the filtered liquor contains, is separable by heat, and the chloric acid dissolved in water remains. Chloric acid may also be obtained by adding dilute sulphuric acid to a solution of *chlorate of baryta*, as long as it occasions a precipitate. The baryta is thus separated in the form of an insoluble sulphate, and the chloric acid remains in aqueous solution. Care must be taken to add no more sulphuric acid than is requisite; for any excess contaminates the chloric acid. If the exact proportion has been used, the chloric acid is neither rendered turbid by dilute sulphuric acid nor by chlorate of baryta. If either of these occasions a precipitate, they must be *carefully* added till the effect ceases; the clear liquid may then be decanted or filtered off. It may be concentrated by cautious evaporation.

Chloric acid is a sour liquid, and of a yellowish tint when highly concentrated. It forms no precipitate in any metallic solution. It reddens vegetable blues, but has no bleaching power. When added to a strong solution of potassa, crystals of chlorate of potassa are deposited. When concentrated, it acts powerfully, and even to ignition, upon paper, and some other dry organic bodies; it decomposes alcohol, with the formation of acetic acid. The most remarkable of its salts, which are now termed *Chlorates*, were formerly known under the name of *Oxymuriates*. When distilled at a high heat, it suffers a partial decomposition, and a portion of chlorine and oxygen are liberated. It is decomposed by hydrochloric and sulphurous acids, and by sulphuretted hydrogen; but those acids which are already saturated with oxygen do not act upon it. Its decomposition by hydrochloric acid is attended with the evolution of chlorine and the formation of water; by sulphurous acid, with the evolution of chlorine and the production of sulphuric acid; and by sulphuretted hydrogen, with the separation of chlorine and sulphur and the formation of water.—(See *Chlorate of Potassa*.) Chloric acid consists of

PERCHLORIC, OXYCHLORIC, OR HYPERCHLORIC ACID, ($C + 7O$) or C'' ,
 ...
 or \bar{C} , was discovered by Count Stadion (*Ann. de Chimie et Phys.*, viii.): it is procured by distilling *perchlorate of potassa* with its own weight of sulphuric acid, diluted with about a fourth part of water. At a temperature of about 280° , white vapours pass off, which condense in the form of a colourless liquid. It is a very stable compound, not decomposed by sulphuric or hydrochloric acid; nor by alcohol or organic bodies. When concentrated, its specific gravity is 1.6, and it boils at 392° . By distilla-

tion with strong sulphuric acid it may be obtained in the solid form and crystallized; in this state it hisses when thrown into water. (GAY LUSSAC. SERULLAS. MITSCHERLICH. *Ann. de Chim. et Phys.*, viii., ix., xlv., and xlix.) It consists of

§ III. IODINE.

IODINE was discovered in 1812 by M. Courtois, a chemical manufacturer at Paris. Vauquelin (*Ann. de Chim.*, xc.), Gay Lussac (*Ibid.*, lxxxviii., xc., and xci.), and Davy (*Phil. Trans.*, 1814), have fully examined its properties.

Iodine is chiefly prepared at Glasgow from *kelp*, which is the fused ash obtained by burning sea-weeds, and is principally manufactured on the west coast of Ireland, and the western islands of Scotland. The long stems of the *Fucus palmatus* are most productive of iodine. "A high temperature in the preparation of kelp, which increases the proportion of alkaline carbonate, diminishes that of the iodine, owing to the volatility of the iodide of sodium at a full red heat. The kelp which contains most iodine, generally also contains most chloride of potassium, and it is for these two products that the substance is now valued, more than for its alkali."—(GRAHAM.)

Iodine may be procured by the following process: Lixivate powdered kelp with cold water. Evaporate the lixivium till a pellicle forms, and set aside to crystallize. Evaporate the mother-liquor to dryness, and pour upon the mass half its weight of sulphuric acid. Apply a gentle heat to this mixture in the flask *a* of the alembic shown in the annexed figure, of which *b* is the head or capital, having a tube issuing from it, and descending into the receiver *c*. Fumes of a violet colour arise, (hence its name, from *ιώδης*, *violaceus*,) and condense in the form of opaque crystals, having a metallic lustre; these are to be washed out of the head of the alembic with a small quantity of water, and quickly dried on bibulous paper.

Iodine may likewise be obtained from soap-makers' *black ash* by a similar process: instead of evaporating the mother-liquor to dryness, the quantity of iodine is sometimes greater when it is merely concentrated, mixed with excess of sulphuric acid, boiled, and filtered: the liquid is then mixed with its weight of powdered black oxide of manganese, and heated in an alembic, or in a flask with a wide tube attached to its neck, when the iodine sublimes as before.

According to Dr. Ure, iodine may be abundantly obtained from the brown residuary kelp-liquor of the soap-boilers, by exposing it to a heat of about 230°, saturating it with sulphuric acid previously diluted with

its bulk of water, and pouring the liquor, when cold, off the crystals which are deposited, and which are chiefly sulphate of soda. Filter this liquor, and to every 12 ounces by measure add 1000 grains of black oxide of manganese in powder; put this mixture into a large matrass with a wide neck, over which a glass globe is inverted, and apply heat with a charcoal chauffer. The less diffusive heat of a lamp is apt to crack the bottom of the matrass, particularly if a large quantity of materials be employed. To prevent the heat from acting on the globular receiver, a thin disc of wood, having a round hole in its centre, is placed over the shoulder of the matrass. As soon as the upper vessel becomes warm, another is to be put in its place, and thus the two may be used in rotation as long as violet fumes arise.

The process as conducted at Glasgow is described by Professor Graham in his *Elements of Chemistry*. Some useful directions respecting it are also given in the *Philosophical Magazine*, XL.

Traces of iodine are found in sea water, in sponge, in several saline springs, and in the coarser varieties of common salt; Vauquelin detected it in some silver ores from Mexico (*Ann. C. & P.*, xxix.); and Bustamente, in a white lead ore from Mexico, and in a species of *Agave*.—(*Ann. C. & P.*, Lxxii.)

Iodine has a bluish-black colour; its lustre is metallic, and its fracture when in a mass is greasy and lamellar. It is a non-conductor of electricity. It is not changed by passing through a red-hot tube, either alone or over charcoal. It is soft and friable. Its specific gravity according to Thomson is 3.08; according to Gay Lussac, 4.946. Its specific heat = 0.05412. (REGNAULT.) It produces a yellow stain upon the skin. Its smell somewhat resembles that of diluted chlorine; its taste is acrid. It is extremely volatile when moist, and in that state produces a pale violet vapour at a temperature between 60° and 80°. At 120° or 130° it rises more rapidly in vapour; at 220° it fuses; and at 350° it boils and produces dense violet-coloured fumes, which condense in brilliant plates, and acute octoëdrons. 100 cubical inches of iodine vapour weigh 270 grains. Its specific gravity, therefore, compared with air, is 8.7, and with hydrogen, 126. The density of iodine vapour, deduced from that of hydriodic acid is 8.7882. (THOMSON.) Like chlorine and oxygen, it is evolved from its combinations at the positive electrode; it renders vegetable colours yellow, and is very sparingly soluble in water, that liquid not holding more than one 7000th its weight in solution. The colour of this solution is pale brown; it gives out no oxygen by exposure to sunshine, nor does it bleach; it however slowly loses its own colour, and gives rise to the formation of *iodic* and of *hydriodic acid*. Iodine is much more soluble in alcohol and in ether, forming deep brown solutions.

The peculiar appearance of the vapour of iodine is in many cases a sufficient evidence of its presence; a more delicate test, however, was discovered by Messrs. Colin and Gaultier de Claubry, in its remarkable property of forming a deep blue insoluble compound with starch. According to Professor Stromeyer, a liquid, containing one 450,000th its weight of iodine, receives a blue tinge when a solution of starch is added to it. To ensure success, the iodine must be in a free state, and the

solution cold, for boiling water destroys the colour; where the proportion of iodine is very minute, a few minutes elapse before the discoloration ensues. (STROMEYER, in GILBERT's *Annalen*, xix. 146.) As the iodic compounds are decomposed by chlorine, it may often be conveniently used as a test of iodine. Thus, when a very minute quantity of iodide of sodium or potassium is present in a solution, the addition of chlorine discolours it, and if a little solution of starch be then added, the iodine is immediately detected by the blue colour. Or any compound containing common salt, and an alkaline iodide, mixed with a solution of starch, and exposed to voltaic action, yields a blue colour at the positive electrode. The equivalent of iodine may be assumed as = 126 (126.3, TURNER; 126.57, GRAHAM).

The principal use as yet made of iodine and its compounds, is in medicine; it powerfully promotes the action of the absorbents, and is chiefly used in glandular diseases, and as an alternative. In overdoses it is an irritant poison. The rich colour of some of its metallic combinations has led to its employment in the art of calico-printing.

Iodine is occasionally adulterated by plumbago, sulphuret of antimony, or peroxide of manganese, but these additions are easily detected by their insolubility in alcohol. The relative quantity of moisture in iodine may be ascertained by heating it in a tube, with twice its weight of fused chloride of calcium, at a temperature not exceeding the boiling-point of the iodine; the iodine may be expelled by a current of air and the increase of weight sustained by the chloride gives the quantity of water.

IODINE AND OXYGEN.—There appear to be four definite compounds of iodine with oxygen; an oxide, and three acids.

OXIDE OF IODINE.—This compound was discovered by Professor Sementini, in attempting the direct combination of iodine and oxygen: a portion of it, he says, is formed when iodine is repeatedly heated in atmospheric air, but it is most rapidly produced by presenting iodine and oxygen to each other at a high temperature. For this purpose, a bladder of oxygen is affixed to one end of a copper tube, so placed as to be heated red-hot by lamps or a small charcoal fire; the other end of the tube terminates in the bulb of a tubulated retort containing iodine, which is also to be heated by a lamp: the oxygen is then propelled through the hot tube into the vapour and upon the hot iodine, and a yellow and very thick oleaginous liquid distils over, of an acrid, disgusting taste and odour, which is the compound in question. It slowly volatilizes in the air, and is very soluble in water and alcohol, producing amber-coloured solutions. Phosphorus and potassium are inflamed by it. It changes the blue of litmus to green. If an alkali be poured into its solution, it is rendered colourless.

IODOUS ACID.—If excess of oxygen, and a considerable degree of heat, be employed in the preceding experiment, the product is partly *iodous acid*. This acid is best obtained by introducing a mixture of one part of iodine and three of chlorate of potassa into a retort, and rapidly applying heat: a dense fluid distils over, which should be collected in a receiver cooled by a freezing-mixture. It has a pungent taste and peculiarly disagreeable odour: its specific gravity exceeds that of water. It reddens litmus, and forms a yellow solution when diluted with water; it slowly

evaporates when exposed to air, and rapidly volatilizes at 112° . It is decomposed by sulphur, disengaging a little heat, and liberating violet vapours; sulphurous acid also decomposes it. Phosphorus and potassium are instantly inflamed by it. It is without action on carbon. It dissolves iodine. Neither its composition, nor that of the oxide, have been accurately determined. (*Quarterly Journal*, xvii. 381: *Ibid. New Series*, i. 477.) It appears probable, from the experiments of Wöhler, that the compound obtained when chlorate of potassa is used, contains chlorine. By the spontaneous evaporation of a solution of iodine in a dilute solution of soda, Mitscherlich obtained prismatic crystals, which by the action of hot water were converted into iodate of soda and iodide of sodium: he considers them as an *iodite* of soda.—(*Ann. de Chim. et Phys.*, xxxvii. 84.)

IODIC ACID ($i + 5o$) or i' , or $\overset{\cdot\cdot\cdot}{\text{I}}$ (DAVY, *Phil. Trans.*, 1815.)—This compound cannot be obtained by the direct action of oxygen on iodine, but it is formed by acting upon peroxide of chlorine by iodine. For this purpose the iodine may be introduced into a small flask, and the peroxide of chlorine disengaged upon it, from a proper mixture of chlorate of potassa and sulphuric acid, with the precautions above pointed out: or 100 grains of chlorate of potassa may be introduced into a small retort, with 400 grains of hydrochloric acid, of the specific gravity 1.105: annex to the retort a small globular receiver, having a bent tube issuing from it, and passing to the bottom of a small flask, containing about 50 grains of iodine; carefully apply the heat of a lamp to the retort, by which oxide of chlorine will be disengaged, and which will be decomposed and absorbed by the iodine. A compound is thus formed, which consists of chloride of iodine and iodic acid. The former is separable by a gentle heat; the latter remains as a white, deliquescent, semitransparent, sour, and inodorous body, very soluble in water, and of a specific gravity exceeding 2. Iodic acid may also be precipitated by slowly adding excess of sulphuric acid, or of alcohol, to the aqueous solution of the perchloride of iodine. This acid is also formed according to Mr. Connell, by boiling iodine for several hours with about five times its weight of strong nitric acid. The mixture should be introduced into a tube closed at one end, and the iodine, as it sublimes to the upper part, constantly returned into the acid, till it disappears: on carefully driving off the nitric acid by heat, the iodic acid remains. Iodic acid is also obtained by the decomposition of *iodate of soda* by sulphuric acid, (SERULLAS, *Ann. de Ch. et Ph.*, xliii. 216,) or *iodate of baryta* may be similarly treated.

The aqueous solution of iodic acid first reddens and then destroys vegetable colours; concentrated by evaporation, it affords a pasty mass, which is *hydrated iodic acid*, which may be crystallised in hexagonal laminæ, and from which the water may be driven off by the careful application of a higher temperature; at about 500° it fuses, and is decomposed into oxygen and iodine. It acts powerfully upon the metals, and with the oxides forms a class of salts called *iodates*. Nitric, sulphuric, phosphoric, and boracic acids, when dropped into a hot saturated solution of iodic acid, form crystals of a yellowish colour, composed of the two acids. (On the Salts of the Iodic Acid, see C. RAMMELSBERG, in *Poggend.* xliv. 525.) It is decomposed by hydrochloric and oxalic acids.

When iodic acid is mixed with charcoal, sulphur, and some other combustibles, it forms compounds which deflagrate when heated: its compounds also deflagrate, like the chlorates, when thrown upon red-hot charcoal. Iodic acid is composed, according to Gay Lussac, of

OXIODIC ACID. PERIODIC ACID. ($i + 7O$), or i'' , or I . When a solution of iodate of soda, mixed with pure soda, is saturated by chlorine, and concentrated by evaporation, a sparingly soluble white salt is obtained, which is a *periodate of soda*: when it is dissolved in dilute nitric acid, and mixed with nitrate of silver, a yellow precipitate falls, which, dissolved in hot nitric acid and evaporated, yields orange-coloured crystals of *periodate of silver*. These crystals are decomposed by cold water, a yellow insoluble *subperiodate* of silver falls, and an aqueous solution of pure periodic acid is formed, which yields crystals of the *hydrated periodic acid* by evaporation, and which, at a temperature above 212° , are resolved into oxygen and iodic acid. (AMMERMÜLLER and MAGNUS: POGGENDORF'S *Annalen*, xxviii. 514.) The periodic acid consists of

IODINE AND CHLORINE. CHLORIDE OF IODINE. CHLORIODIC ACID.—When chlorine is conducted into a vessel containing iodine, it is quickly absorbed, and a compound obtained, which is brown when the iodine is in excess, colourless when exactly saturated, and yellow if there be excess of chlorine. It is volatile, and may be distilled without decomposition. It tastes sour, and powerfully reddens litmus: it attracts moisture from the air, and dissolves readily in water, forming a brown solution when there is excess of iodine. It appears to decompose water, and to form hydrochloric acid and a compound of iodine and oxygen; but these combinations are not permanent, for, on evaporation, chlorine is evolved, and iodine liberated. The saturated compound is regarded as containing one volume of iodine, and two of chlorine. (BERZELIUS, i. 258.) Sir H. Davy (*Phil. Trans.* 1814, p. 487) described the crystalline compound obtained by subliming excess of iodine in chlorine, under the name of *chlorionic acid*, and regarded it as a compound of one proportional of iodine and one of chlorine. It forms no permanent compounds with salifiable bases.

The experiments of Dumas and Serullas seem to prove the existence of two compounds of chlorine and iodine, formed by passing chlorine over iodine. The *protochloride* is soluble without decomposition, in water, alcohol, and ether; but the *perchloride* is resolved by water into hydrochloric and iodic acids, the latter of which may be thrown down by sulphuric acid, or by alcohol. The exact composition of these chlorides has not yet been ascertained. (SOUBEIRAN, *Journ. de Pharm.*, Feb. 1837; KANE, *Phil. Mag.*, x. 430.)

§ IV. BROMINE.

THIS singular substance, first described in the *Annales de Chim. et Physique*, for August, 1826, was discovered by M. Balard of Montpellier. Bromine was originally obtained from the uncrystallizable residue of sea-water commonly called *bittern*; a current of chlorine passed through this liquid immediately gives it an orange tint, in consequence of the evolution of bromine from its combinations: a portion of sulphuric ether is then shaken up with it, which, as it separates upon the surface, is found to have abstracted the bromine, and acquired a reddish-brown tint. The ethereal solution is agitated with solution of potassa, by which bromate of potassa and bromide of potassium are formed, and the whole being evaporated to dryness, and exposed to a dull-red heat, leaves *bromide of potassium*. The solution of this salt is decomposed by passing chlorine into it, or by mixing it with a strong solution of chlorine; chloride of potassium is formed, and the bromine, being volatile, may be separated by distillation, and condensed in a receiver cooled by ice.

Bromine probably exists in sea-water in the state of bromide of magnesium, but its relative proportion is exceedingly minute. One hundred pounds of sea-water taken up at Trieste, afforded, by M. Balard's process, 5 grains of bromide of sodium = 3·3 grains of bromine. It would appear, that in the sea-water at Trieste the bromine is unaccompanied by any iodine; and the same is the case, according to M. Hermbstadt, with the waters of the Dead Sea. In the water of the Mediterranean, on the contrary, iodine is always found with bromine. Bromine is most readily recognised by evaporating the water, so as to separate all its more ordinary crystallizable contents, reducing the remainder to a very small bulk, and dropping in a concentrated solution of chlorine. In the absence of iodine, which may be detected by starch, the appearance of a yellow tint announces bromine. It has thus been discovered, not only in the waters of the ocean, but in certain salt springs, in the ashes of marine plants, and in those of some marine animals. Among the saline springs most abundant in bromine are those of Theodorshall, near Kreutznach in Germany; these are now the chief source of bromine as an article of commerce.

At common temperatures and pressures bromine is a deep reddish-brown liquid, of a peculiarly suffocating and disagreeable odour, whence its name (from *βρωμος*, *graveolentia*). Its specific gravity is about 3. It emits a brownish-red vapour at common temperatures, and boils at 116°. At a temperature somewhat below 0° it congeals into a brittle solid. It is a non-conductor of electricity, and appears in the Voltaic circuit at the positive electrode. It suffers no change by transmission through red-hot tubes. It dissolves sparingly in water, and forms under certain circumstances a definite *hydrate*, which according to Löwig (POGGENDORF's *Annalen*, xiv. 114) is obtained by exposing bromine with a small quantity of water to a temperature of 32°; red octoëdral crystals of the *hydrate of bromine* are then deposited, which continue permanent at the temperature of 50°. At a higher temperature they decompose into liquid bromine and aqueous solution of it. The hydrate is also obtained by passing the vapour of bromine through a moistened tube cooled nearly to the freezing-point. Bromine dissolves in alcohol, and more abundantly in ether. It destroys

vegetable colours. When a burning taper is immersed into its vapour it is speedily extinguished, the flame previously assuming a green and red tint. Phosphorus spontaneously inflames in its vapour; tin and antimony also burn in it; and it combines with potassium with explosive violence. Its action on alkaline solutions will be found analogous to that of chlorine and iodine. It stains the skin of a yellow colour; acts with energy upon most vegetable and animal substances; and is fatal to animal life; a single drop placed upon the beak of a bird immediately killed it. The specific gravity of its vapour has not been correctly determined, but its equivalent number appears, from Berzelius' analysis of bromide of silver, to be about 78, which ought also to express its specific gravity in vapour compared with hydrogen. The density of its vapour compared to air, will, therefore, be about 5·4, and 100 cubical inches should weigh about 167 grains. According to Dr. Thomson the density of bromine vapour theoretically deduced is 5·555. The alcoholic solution of bromine, and the bromide of sodium are occasionally used in medicine: and from its powerful action, there can be no doubt that it must contribute to the medicinal virtues of the mineral waters in which it exists.

BROMINE AND OXYGEN—BROMIC ACID. ($b + 5 o$) or b' , or Br. One compound only of bromine and oxygen has as yet been discovered, namely, the *bromic acid*. Bromic acid is obtained by the decomposition of a solution of *bromate of baryta* by sulphuric acid: sulphate of baryta is precipitated, and a solution of bromic acid obtained, which may be concentrated by slow evaporation; at a high temperature it is partly decomposed, and it cannot be obtained anhydrous. It is sour, inodorous, and first reddens, and then destroys the blue of litmus. It is partially decomposed by concentrated sulphuric acid, but not by nitric acid. It is decomposed by sulphurous acid, by sulphuretted hydrogen, and by hydriodic and hydrochloric acids. From the analysis of bromate of potassa there can be no doubt that the bromic acid is analogous in composition to the chloric and iodic acids, and that it consists of

Bromine	...	1	..	78	..	66·1
Oxygen	..	5	..	40	..	33·9
<hr/>						
Bromic acid	..	1	..	118	..	100·0

CHLORIDE OF BROMINE.—By passing chlorine through bromine, and condensing the vapours at a low temperature, a reddish-yellow fluid is obtained, having a penetrating odour and disagreeable taste. It is very fluid and volatile, emitting yellow vapours; it dissolves in water, and the solution destroys vegetable colours: it would appear, therefore, not to decompose water. Chlorine decomposes most of the compounds of bromine, and hence is useful as a test of its presence. When, for instance, aqueous chlorine is dropped into a weak solution of bromide of potassium, or of sodium, the evolution of bromine is manifested by the deep yellow colour that is produced, and by the odour of the vapour of bromine.

IODIDE OF BROMINE.—Iodine and bromine probably combine in two proportions, but the compounds have not been analyzed. In certain proportions (probably one proportional of iodine and one of bromine) a solid body is obtained, which yields reddish-brown vapours when heated, and these readily condense into arborescent crystals. A further addition of

bromine dissolves these, forming a dark-coloured liquid, soluble in water, possessed of bleaching qualities, and yielding bromides and iodides with the alkalis.

Chlorine, iodine, and bromine, are occasionally so associated as to require separation in analyses. To ascertain the quantity of iodine in the mixed chlorides and iodides of mineral waters, Rose recommends precipitation by nitrate of silver; the mixed chloride and iodide of silver thus thrown down is fused, weighed, and afterwards heated in a tube and a stream of chlorine passed over it; the iodine is thus expelled, and the whole converted into chloride of silver; this is weighed again, and a loss is found to have taken place in consequence of the equivalent of the expelled iodine being greater than that of the expelling chlorine; this loss, multiplied by 1.389, gives the quantity of iodine originally present, and which has been replaced by the chlorine. Schweitzer recommends the adoption of a similar method for estimating the quantity of iodine when mixed with bromine; in this case the mixed iodide and bromide of silver is to be heated in an atmosphere of bromine vapour, by which the iodine is expelled. But the accurate determination of the relative quantities of chlorine, bromine, and iodine, in cases where their combinations are blended, is a problem of much difficulty.

§ V. FLUORINE.

THIS substance has not hitherto been obtained in an insulated state, for its powers of combination are such, that no body has been found capable of resisting its energetic action. The evidence of its existence, as a distinct electro-negative element, will be more clearly understood by reference to the account of its compound with hydrogen (See HYDRO-FLUORIC ACID), and to the experiments of Sir H. Davy (*Phil. Trans.*, 1813, p. 263, and 1814). Its equivalent number is probably = 16. It is found as a component part of a few mineral substances only; one of these, however, commonly called *fluor-spar*, is very abundant and appears to be a compound of fluorine and calcium, or a *fluoride of calcium*. Traces of fluorine are supposed to have been found in bone and in the enamel of teeth. No compound of fluorine with oxygen, chlorine, iodine, or bromine, has yet been satisfactorily shown to exist*.

It may be remarked of the bodies which have been above described that although they do combine with each other, they are not possessed of powerful mutual affinities; and, consequently, their compounds are, with few exceptions, either unstable, or easily decomposed; this is what might be expected as a consequence of their analogous electrical relations; for they are all apparently evolved at the anode in Voltaic arrangements. Yet, in respect to each other, it has been supposed that they may exhibit opposite, though feeble electrical energies, and that such compounds, in Voltaic decomposition, may thus present one of their elements at the negative electrode; a mixed solution, for instance, of bromine and iodine, when electrically decomposed, is stated to evolve

* Baudrimont, and the Messrs. Knox, have each published experiments by which they state that fluorine may be isolated. (*Phil. Mag.* 3rd series, vol. ix. x. and xii.) "But more than one skilful chemist of name has been less fortunate in obtaining indications so decisive, of the isolation of fluorine." (GRAHAM.)

bromine at the positive, and iodine at the negative surface, and it has hence been concluded, that iodine is electro-positive in respect to bromine; but the possible influence of secondary electro-chemical action, in these cases, has not been taken into the account. The compounds of the bodies above described with hydrogen and with the metals, when subjected to electrical decomposition, give up the inflammable body at the negative pole, or cathode, while the supporter of combustion appears at the positive pole, or anode.

§ VI. HYDROGEN.

HYDROGEN was first duly examined in a pure state by Mr. Cavendish, in 1766. (*Phil. Trans.*, vol. lvi. 144.) It had before been confounded with several of its compounds, under the name of *inflammable air*: the term *hydrogen* was given to it by the French chemists in consequence of its being one of the elements of water (from *ὕδωρ*, *water*, and *γεννέω*, *to generate*). It also forms a component of all vegetable and animal products, and is therefore abundantly diffused throughout nature.

Hydrogen gas may be obtained by the action of iron or zinc upon dilute sulphuric acid. Some pieces of iron-wire, or of zinc, may be introduced into the tubulated flask *a* (fig. 225), and covered with sulphuric acid diluted with six times its bulk of water; an effervescence ensues, heat is evolved, and the gas escapes by the bent tube *b*, inserted by grinding into the neck of the flask, and may be collected in the hydro-pneumatic apparatus. The hydrogen, however, which is thus obtained, is never perfectly pure. When procured by the means of iron, its odour is peculiarly disagreeable, in consequence, according to Berzelius (*Lehrbuch*, 186), of its containing a portion of volatile oil, formed by its union with a minute quantity of carbon which all common iron contains. When such gas is passed through alcohol, much of the odour is absorbed by it, and on diluting it with water, it becomes milky. Obtained by means of zinc, the gas is perhaps somewhat more pure, but it appears to hold a trace of zinc in solution, and often traces of sulphur and of arsenic. For the purposes of delicate experiments, hydrogen must be passed through a solution of potassa, then dried by passing it through a tube containing fragments of fused chloride of calcium; it should also be collected over mercury, and procured from purified zinc, and sulphuric acid so far diluted as to act but slowly upon the metal. The hydrogen liberated by the Voltaic decomposition of water by platinum surfaces (see WATER), may, when dried, be considered as absolutely pure. Upon the same principle it may be obtained by inverting a platinum crucible in dilute sulphuric acid, and placing a plate of zinc upon it; the hydrogen is then evolved by the Voltaic action of the two metals, and a portion of it collects within the crucible. This gas is also in a state of extreme purity when liberated from pure water by the action of an amalgam of potassium or of sodium.

Hydrogen is an uncondensable æriform fluid, not absorbable by water, unless that liquid has been previously deprived, by boiling, of common air, in which case 100 cubic inches dissolve about 1.5 cubic inches of

the gas. It has no taste, and when perfectly pure, is inodorous, but it usually has a slight disagreeable smell. It has great power of refracting light (p. 193.) It may be respired for a short time, though it is instantly fatal to small animals. M. Maunoir, after having breathed a quantity of pure hydrogen, found that his voice had become remarkably shrill. (*Phil. Mag.*, iv. 214.) The intensity of sound is greatly diminished in an atmosphere of hydrogen; Leslie, indeed, found it more feeble than its rarity compared with air would have led him to expect. He placed a piece of clock-work by which a bell was struck every half minute under the receiver of the air-pump, and, after exhausting the air, filled the receiver with hydrogen, but the sound was then even feebler than in the highly-rarified atmosphere. (*Ann. Philos.*, 2nd series, iv. 172.) It is stated that sound moves at least three times as fast in hydrogen as in air.

Hydrogen gas is the lightest known form of matter, and its equivalent or atomic weight is below that of all other substances, it is, therefore, conveniently assumed as *unity* in speaking of the specific gravity of gases, as well as in referring to the proportions in which bodies combine. In consequence of its extreme lightness, it is difficult to determine its weight with accuracy by the common process; but the researches of Berzelius and Dulong, and of Dr. Prout, lead us to infer that its specific gravity, compared with oxygen, is as 1 to 16: 100 cubic inches, therefore, of pure hydrogen gas at mean temperature and pressure weigh only 2.1318 grains, and compared with air, its specific gravity is as 0.0694 to 1. At the temperature of 32° 100 cubic inches weigh 2.22756 grains. (THOMSON.)

The low specific gravity of hydrogen is well and amusingly illustrated by substituting it for common air, in soap bubbles, which then rapidly ascend in the atmosphere, and may be kindled by the flame of a taper. The same circumstance also led to its employment for the inflation of balloons, which, however, have of late years been generally filled with coal-gas. Small balloons may be purchased, made of gold-beater's skin, or of the lining membrane of the crop of a turkey, which, when filled with pure hydrogen, rise to the ceiling, their specific gravity being inferior to that of the surrounding air. Some of these when filled with hydrogen, do not weigh more than 42 grains, while the same bulk of air would weigh 52 grains, so that their buoyant power is about = 10 grains.

Hydrogen is inflammable, and extinguishes flame. When pure, it burns quietly, with a lambent blue flame at the surface in contact with air; but, if mixed with thrice its volume of air, it burns rapidly, and with detonation. In making this experiment, a strong phial, capable of holding about six ounces of water, may be employed; or the *inflammable air-pistol*, which admits of the mixture being fired by the electric spark. This instrument consists of a cylinder of brass, about three-fourths of an inch diameter, and six inches long, in the form of a small cannon or pistol-barrel, properly mounted and having a wire, *a* (fig. 226), at the part usually occupied by the touch-hole, passing through a

tube of ivory, *b*, and not quite touching the interior of the cylinder; an electric spark communicated to this wire inflames the mixture of hydrogen and atmospheric air in the interior. It may be charged, by previously filling it with dry sand, and emptying it out into a phial of hydrogen, which then rises into the gun sufficiently mixed with air; the muzzle may be secured by a cork, which is expelled with much violence and a loud report, upon the inflammation of the gas.

The electrical air-gun may be also charged, by holding it for a moment over the open jet of the following instrument, (fig. 227,) always taking care that there is a due admixture of atmospheric air, otherwise the electric spark will not inflame it. *a* is a funnel-shaped vessel, fitting by a ground-joint into the three-necked bottle *b*; to the stopper *c* is annexed a brass wire, with a cylinder of zinc screwed upon its lower end; *d* is a tube furnished with a stopcock and jet-pipe; the capacity of the vessel *a* should be nearly equivalent to that of *b*, and may contain from one to three or four pints. To charge this apparatus with hydrogen, *b* is three-fourths filled with water, and the stopper *c* being removed, a quantity of sulphuric acid, previously diluted with its bulk of water, is poured in by a long funnel, so that it may remain at the bottom of the water which now fills the vessel. The stopper *c*, with its appended piece of zinc, is then put in, and the generated hydrogen forces the dilute acid into *a*, where its pressure serves to propel the gas through *d*, whenever the stop-cock is opened; the acid, at the same time descending, produces a fresh portion of hydrogen by again acting upon the zinc. This instrument is useful where small quantities of hydrogen are required for burning, charging air-guns, and other purposes.

Volta's air-lamp, in which a jet of hydrogen is inflamed by a small spark, furnished by an electrophorus concealed in the foot of the apparatus, also furnishes an elegant illustration of the ready inflammability of hydrogen by the electric spark.

In examining into the quantity of atmospheric air required to form an explosive mixture with hydrogen, Mr. Cavendish found the loudest report was produced by two volumes of hydrogen with six of air. One of hydrogen with nine of air burned very feebly, and four of hydrogen with one of air burned without explosion. (*Phil. Trans.*, Lvi.)

The inflammability, as well as the low specific gravity of hydrogen, are shown in the following experiments:—Let a jar filled with this gas stand for a few seconds, with its open mouth upwards; on letting down a candle, the gas will be found to have escaped, and to be replaced by common air. Place another jar of the gas inverted, or with its mouth downwards; the gas will now be found to remain a short time in the jar, being prevented from escaping upwards by the bottom and sides of the vessel. (HENRY.) Provide an air-jar, with a stopcock and jet, and fill it with hydrogen, upon the shelf of the pneumatic trough; then set fire to the gas at the jet, and whilst it is there burning, slowly lift the jar out of the water, and hold it firmly by the brass cap. The flame will continue for

some time at the jet, the hydrogen being propelled through it by its lightness; but when the air becomes mixed in such proportions with the gas as to form an explosive mixture, the flame recedes through the jet, and the whole kindles suddenly. (BERZELIUS.) Hydrogen may in fact be decanted, as it were, *per ascensum*, from one jar into another held above it. Thus, if a light bell-glass be suspended with its mouth downwards to one end of a scale-beam, and accurately counterpoised, it will be found, on placing a jar of hydrogen gas closed by a plate of glass underneath it, that the hydrogen, on removing the glass plate, will ascend into the bell, and, by its lightness, cause the counterpoise to sink; the hydrogen may also be inflamed by a taper introduced into the counterpoised bell.

If, instead of a mixture of hydrogen and atmospheric air, two volumes of hydrogen mixed with one of *oxygen* be burned in the air-gun, or in a stout and small phial, the explosion is extremely violent; but if the mixture be diluted with eight measures of hydrogen, or with nine of oxygen, it becomes unflammable.

If a current of hydrogen be inflamed when issuing from a small aperture, and a tube of eighteen or twenty inches in length be held over the flame, as in fig. 228, a peculiar musical tone is produced, varying in its pitch with the length and diameter of the tube, and the extent to which the flame, which should be very small, is introduced within it. This effect is not peculiar to hydrogen, but is produced by a variety of other flames (FARADAY, *Journal of Science and the Arts*, vol. v.), and is referable to the succession of explosions and consequent vibrations produced by the combustion of the gas in the tube.

The tendency which gaseous fluids have to become completely mixed under all circumstances, and as it were to penetrate each other, is well illustrated where hydrogen is employed. Thus, if two small phials, the one containing oxygen and the other hydrogen, be connected perpendicularly by a long glass tube, of small bore, it will be found, that although the hydrogen be uppermost, and much lighter than the oxygen, it will, in the course of a few hours, have perfectly mixed with the oxygen, and the gases will be found in equal proportions in both phials: hence the expression that one gas acts as a vacuum with respect to another. (DALTON, *Manchester Memoirs*, vol. i., New Series.)

The facility, too, with which hydrogen passes through crevices, fissures, and capillary tubes, as also through membranes and various organic tissues, is very remarkable. Attention was first called to this subject by a curious observation of Döbereiner on the escape of hydrogen through a small crack or fissure in a glass jar, which had been filled with the gas, and placed upon the shelf of the pneumatic trough; to his surprise, the water rose in the jar nearly three inches above the level of that in the trough. The subject was afterwards investigated by Professor Graham, who published a masterly essay upon it in the *Edinburgh Philos. Trans.* (xii. 222.) The following is an abstract of his inquiries, abridged from his *Elements of*

Chemistry. On examining Döbereiner's result, he found that while the hydrogen escaped outwards, a portion of air penetrated inwards, amounting to between one-fourth and one-fifth of the volume of the lost hydrogen: that, in fact, when hydrogen communicates with air by such a chink, there is a powerful disposition to mutual intermixture; "a particle of air, however, does not interchange with a particle of hydrogen of the same magnitude, but of 3.83 times its magnitude. We may adopt the word *diffusion-volume* to express this diversity of disposition in gases to interchange particles, and say that the diffusion-volume of air being = 1, that of hydrogen gas is = 3.83. Now every gas has a diffusion-volume peculiar to itself, and depending upon its specific gravity: of those gases which are lighter than air, the diffusion-volume is greater than 1, and of those which are heavier, the diffusion-volume is less than 1."

Professor Graham's results were obtained by what he calls a *diffusion-tube*; it is a graduated glass tube of about half an inch diameter, and fourteen inches long; one end is closed by a plate of plaster of Paris of about one-fifth of an inch thick; it may be used over mercury or water, but in the latter case care must be taken in filling it, to keep the plaster plug dry. When this tube is filled with hydrogen gas, standing over water, the gas diffuses into the atmosphere through the pores of the stucco, the water rises proportionately in the tube, and in about half an hour, the whole of the hydrogen will have escaped, and a certain quantity of common air entered: in experiments for determining the proportion of gas diffused and of replacing air, inequality of pressure must be guarded against by placing the diffusion-tube in a jar of water which must be filled up in proportion as it rises in the tube, and the inner and outer levels kept equal. Assuming the diffusive power of air as = 1, that of hydrogen is = 3.8; of oxygen = 0.9; of nitrogen = 1.014.

Cork, spongy platinum, and other porous substances, may be substituted for the stucco, in the diffusion-tube; or a piece of bladder, or thin caoutchouc, may be used. With the latter a very striking experiment, illustrative of this form of *endosmose* and *exosmose*, may be made as follows:—confine a portion of common air in a tumbler or wide-mouthed jar, by tying it carefully over with a piece of thin sheet-caoutchouc, and place it under a large bell-glass filled with hydrogen gas, and standing in a dish of water: the hydrogen will gradually find its way through the caoutchouc and act upon it with such elastic power as forcibly to distend and even ultimately burst it. If the small jar be filled with hydrogen, and the larger one with air, an opposite result will ensue, as shown by the concave instead of convex surface assumed by the elastic diaphragm. Upon the same principle, if a thin flaccid bladder, containing common air, be suspended in a jar of carbonic acid, it will become distended to the utmost by the entrance of the carbonic acid from without: or if the bladder distended with carbonic acid be suspended in the air, it will become flaccid, in consequence of the *exosmose* of the former prevailing over the *endosmose* of the latter.

It has been shown that gases flow into a vacuum with velocities which are inversely as the square roots of their densities; that is, with velocities corresponding to the numbers which express their diffusion-volumes: hence the law of diffusion has been regarded by Mr. T. S. Thomson (*Phil.*

Mag., 3rd series, iv. 321) as confirming Dalton's theory, that gases are inelastic towards each other; a conclusion, however, which Mr. Graham hesitates to adopt. (*Elements of Chemistry*, p. 75.)

In discussing the nature of flame and the causes of their luminosity and heat (p. 223,) I have alluded to the high temperature of that of hydrogen; it is occasionally employed for exciting intense heat; and, when mixed with oxygen, and burned as the mixture issues from a small jet, it excites a temperature nearly equal to that of the arc of flame in the voltaic circuit. A blow-pipe upon this construction was first made by Mr. Newman, and afterwards improved, as to its safety, by Professor Cumming, of Cambridge. (*Journal of Science and the Arts*, i. 65, and ii. 380.) A full account of the construction and use of this hydro-oxygen blow-pipe will be found in Dr. Clarke's book upon the subject. (London, 1819.) Mr. Hemming's safety-tube may also be used in these experiments. (See *Phil. Mag.*, 3rd series, i. 82.) An excellent mode of obtaining intense heat by the combustion of oxygen and hydrogen, consists in propelling them from separate air-holders through a burner composed of two concentric tubes: a good form of which has been contrived by Mr. Daniell. (*Phil. Mag.*, 3rd series, ii. 57.) The apparatus for this purpose has also been further improved by Mr. Maugham, especially as relates to its application to the solar microscope. (*Trans. Soc. Arts, &c.*, vol. L.)

HYDROGEN AND OXYGEN. WATER. PROTOXIDE OF HYDROGEN. ($h + o$)

or q , or \dot{H} .—The discovery of the composition of water, one of the most important in the science of chemistry, was made by Cavendish, in 1788. (*Phil. Trans.*)

When *two volumes* of pure hydrogen gas are mixed with *one volume* of pure oxygen gas, and the mixture inflamed in a proper apparatus by the electric spark, the gases totally disappear, and water equal in weight to the gases consumed is formed: and again, if water be exposed to electrolytic action, it is resolved into *two volumes* of hydrogen, disengaged at the negative pole or cathode, and *one volume* of oxygen, disengaged at the positive pole or anode (see p. 302); so that water is thus proved by *synthesis*, and by *analysis*, to consist of two volumes of hydrogen, combined with one volume of oxygen. The specific gravity of hydrogen, compared with oxygen, is as 1 to 16; these numbers, therefore, represent the comparative weights of equal volumes of those gases; but as water consists of *one volume of hydrogen and half a volume of oxygen*, it is obvious that the relative *weights* of those elements will be as 1 : 8, or as follows:—

	Atoms.	Weights.	Per cent.	Volumes.
Hydrogen . . .	1 . . .	1 . . .	11.1 . . .	1.0
Oxygen . . .	1 . . .	8 . . .	88.9 . . .	0.5
Water . . .	1 . . .	9 . . .	100.0	

The experiments illustrating the composition of water, and showing the proportions in which its elements are united, may be divided into *synthetic* and *analytic*. Among these the following may be selected:—

Synthetic Experiments.—i. Burn a current of hydrogen under the copper funnel *a*, represented in the following wood-cut, fig. 229; by

uniting with the oxygen of the atmosphere it will produce aqueous vapour, which passing into the glass cylinder *b*, will condense in drops*.

ii. If two measures of pure hydrogen be mixed with one of pure oxygen, and detonated in the graduated glass tube *a*, fig. 230, standing over water or mercury, by an electric spark passed through the platinum wires *b b*, the gases will entirely disappear. If there be any excess of either of the gases, the portion in excess will remain unconsumed. At the moment the explosion takes place the gaseous mixture becomes greatly expanded, probably to fifteen times its original bulk (DAVY on *Flame*, p. 90), and a portion is apt to escape at the bottom of the tube; hence the advantage of performing the experiment over mercury in the form of apparatus recommended by Dr. Ure. (See EUDIOMETER.)

iii. The same experiment may be thus varied. A (fig. 231) is a very strong and thick glass vessel provided with a glass stop-cock *E*, and with a ground stopper firmly secured by the brass collar *c*, through which the platinum wires *D D* pass. The vessel *A*, previously exhausted of air, is placed upon the bell-glass *B*, in the pneumatic trough, containing a mixture of pure oxygen and hydrogen in the above-mentioned proportions. Upon opening

* On examining the water thus produced, it is generally slightly acid from the presence of nitric acid, derived from the nitrogen in the atmosphere; if hydrogen be in excess it sometimes contains ammonia. (SAUSSURE, *Ann. de Chim.*, LXXI, p. 282.)

the stop-cocks *E F*, a quantity of the mixed gases passes into *A*, where, *after having carefully closed the stop-cocks*, it may be inflamed by an electric spark passed through the platinum wires. At the instant of the detonation, a vivid flame pervades the upper vessel, and it becomes lined with moisture. If the stop-cocks be again opened, a fresh portion of the mixed gases enters, and may be inflamed as before.

iv. A mixture of oxygen and hydrogen gases, suddenly submitted to violent mechanical compression, unite with combustion, and produce water. (BIOT.) Under a more gradual compression, equivalent to that of 50 atmospheres (by sinking the mixed gases in a tube, sealed by mercury, to a depth of 540 metres in the sea), the gases do not unite. (DELAROCHE.) Water may also be produced by heating the mixed gases to a temperature below that required for their combustion with flame. (DAVY on Flame, p. 68.) According to Grotthus, no explosion takes place in a mixture of two volumes of hydrogen and one of oxygen, expanded to six times its volume by heat, or to sixteen times its volume by diminished pressure. (*Ann. de Chim.* lxxxii.) Electric sparks, however, passed for some time through such a mixture, gradually produce water. A red heat, visible by day light, inflames the mixture;

but a very dull red heat only causes the combination of the gases without explosion. Mr. Graham states, that if a mixture of oxygen and hydrogen be heated in a vessel containing a quantity of pulverised glass, or any sharp powder, they begin to unite, in contact with the foreign body, in a gradual manner, without explosion, at a temperature not exceeding 660°.

v. A very curious discovery connected with the present subject was made in the year 1824, by Professor Döbereiner, of Jena, who found that spongy platinum, (see PLATINUM,) possessed the singular property of causing the immediate combination of hydrogen and oxygen, with heat sufficient to inflame the gases, and of course to render the metal red-hot. If a small piece of well-prepared spongy platinum be held in a jet of hydrogen issuing from a small tube into the atmosphere, it immediately becomes hot enough to inflame the gas. If a mixture of oxygen and hydrogen, or of atmospheric air and hydrogen, not in explosive proportions, be submitted to the action of the platinum, it disposes the gases to slow combination, water is gradually formed, and if there be a sufficiency of oxygen, the whole of the hydrogen disappears under its influence; if, on the other hand, there be excess of hydrogen, the oxygen disappears. In analyzing certain gaseous mixtures, therefore, platinum, in this peculiar state of mechanical division, becomes a most valuable agent. For more convenient application to such purposes, the platinum may be mixed with an equal weight of pure clay, and moulded with a little water into small balls, which must be carefully dried at a high heat. These

may be conveniently thrown up into gases standing over mercury, and their power is not impaired by use; for they may always be rendered efficient, or their power restored, by heating them in the flame of a blow-pipe. Spongy platinum also causes the union of oxygen with several other gases, such as with carbonic oxide, and, at high temperatures, with olefiant gas; it also promotes the decomposition of nitric oxide by hydrogen. (DULONG and THENARD, *Ann de Chim. et Phys.*, xxiii. 440.) A very few other metals operate in the same way, but less perfectly than platinum, such as palladium and iridium. Gold and silver in fine leaves are efficient at temperatures above 212° .

vi. The extraordinary effects observed by Mr. Faraday respecting the action of the platinum which had formed the positive pole of the voltaic pile upon a mixture of oxygen and hydrogen gases, and which he has detailed and investigated in the sixth series of his *Experimental Researches in Electricity*, (*Phil. Trans.*, 1834, p. 55,) are apparently of the same nature as those observed by Döbereiner. He refers them to a peculiar attraction between the *perfectly clean* metallic surface and the particles of the gaseous mixture, resembling that by which bodies become *wetted* by fluids with which they do not combine chemically, or in which they do not dissolve; or the attraction which renders certain bodies hygrometric, though they neither dissolve in, nor combine with, water; or lastly, to a kind of attraction analogous to that between air and glass, so well known to barometer-makers. It may be conceived that by some such attractive force the particles of the oxygen and hydrogen become so approximated, and deprived of their gaseous repulsion, as to enter into chemical combination, and in so doing to evolve the heat which raises the temperature of the metal.

Analytic Experiments.—Water may be decomposed, or resolved into its elements, by a variety of processes, of which the following will suffice for our present illustration:—

i. *a* (fig. 232) is a glass retort, into which is introduced a given weight of water; *b b* a small furnace through which passes the porcelain tube *c c*, which terminates in the spiral pewter tube *d d*, immersed in water. A given weight of pure iron-wire, coiled up, is introduced into the tube *c*, and the whole made red-hot; the water in *a* is then made to boil, and the vapour, on coming into contact with the red-hot iron, is in part decomposed; the oxygen is retained by the iron; and the hydrogen, escaping through the tube *f*, may be collected as usual. Any undecomposed portion of water is condensed in the worm-pipe *d*, and drops

into the vessel *c*. After this experiment the iron will be found to have increased in weight; and if attention be paid to the quantity of water which has collected in *c*, and to the weight of the hydrogen gas evolved, it will be found that the weight gained by the iron, added to that of the hydrogen, will be equal to the weight of the water which has disappeared. Lavoisier concluded, from an experiment thus conducted, that water consisted of 85 parts by weight of oxygen, and 15 by weight of hydrogen: that is, that for every 15 grains of hydrogen gas evolved, 85 grains of oxygen were condensed by the iron.

ii. Decomposition by voltaic electricity best illustrates the composition of water, since it exhibits both the oxygen and hydrogen in the gaseous form. The annexed wood-cut represents a section of an apparatus for this purpose. It is a glass vessel containing water, having two wires of platinum, *a a*, passing through its bottom, which terminate in two narrow plates or strips of platinum, *a' a'*, which rise up into, and over which are inverted, the tubes *b b*, also filled with water. The wires are now connected with a moderately-powerful voltaic apparatus: oxygen is evolved at the positive, and hydrogen at the negative electrode, which gases rise into the tubes, and it is seen that one volume of oxygen, *o*, and two volumes of hydrogen, *h*, are the constant results*. If these gases be mixed and

* By passing electric discharges from a Leyden jar by two fine wires through water, oxygen and hydrogen are evolved at both; the decomposition therefore, is apparently not electropolar. In the electrolysis of water, as described in the text, the bubbles of hydrogen are larger and rise more regularly than those of oxygen, which are much more minute and diffused; a deficiency in the oxygen is also occasionally remarked, which, when the proportion of sulphuric acid added to improve the conducting power of the water exceeds that above mentioned, is sometimes considerable: it probably arises from the solution of a portion of the oxygen in the dilute acid, or from the formation of oxy-water. Mr. Faraday recommends for the Voltameter (p. 314), an acid of the specific gravity of 1.3. From a mixture of two measures of sulphuric acid and one

of water he obtained 42 volumes of hydrogen and only 12 (instead of 21) of oxygen. (*Researches*, vii., § 728.)

If the water used for voltaic decomposition be not perfectly pure, its impurities are shown by the production of acid and alkaline matter at the positive and negative pole. (See p. 306.) But pure water is so imperfect an electrolyte that, in the above experiment, it is convenient to render it more easy of decomposition by the addition of a little sulphuric acid. (See page 302, and note.) In using any apparatus, such as the voltameters, in which water is decomposed by platinum electrodes, care must be taken that no part of the clean electrode be exposed to the evolved gases, as it will tend to induce their recombination, and in so doing sometimes becomes red-hot and cause explosion.

detonated, pure water is again formed. In employing this apparatus the conducting power of the water requires to be augmented by the addition of about a tenth part of sulphuric acid.

Properties of Water.—Water, in its ordinary state, such as *spring* and *river water*, is always so far contaminated with foreign substances as to be unfit for many chemical purposes, and frequently, as will be more fully shown hereafter, even for domestic use. *Rain-water* is much more pure, but it always contains small quantities of carbonic acid and of atmospheric air, besides appreciable traces of vegetable or animal matter; to the latter it owes its property of becoming putrid when kept. Hassenfratz asserts that snow-water contains excess of oxygen.—(*Jour. de l'Ecole Polytech.*, cap. iv., 570.) Rain-water collected near the sea shows traces of chlorine. The distinction of water into *hard* and *soft* has reference to its less or greater purity. The impurities of water are

234

separated by *distillation*, which process is usually conducted upon the large scale in a copper *boiler*, *a*, placed either in a portable furnace (fig. 234), or set in brickwork, according to its dimensions, to which is annexed the *still-head*, *b*, of the same material, or of pewter, connected with the pewter *worm* *c*, which is immersed in the *worm-tub*, or *refrigerator*, *d*, its lower end passing out at *e*. The water in this vessel must always be retained of a low temperature, to effect the condensation of the vapour in the spiral tube.

Distilled water, as commonly prepared, always affords minute traces of foreign matter, especially when subjected to Voltaic decomposition, and can only be considered as *perfectly* pure when re-distilled at a low temperature in silver vessels. (See page 308.)

Pure water is transparent, and without either colour, taste, or smell. It is a powerful refractor of light, and a very imperfect conductor of heat

(p. 156) and of electricity (p. 245). In consequence of the facility of obtaining it pure, it is assumed as a standard to which the relative weight of all other bodies may be compared, its specific gravity being called $= 1.000$; and hence the importance of estimating its weight with precision (p. 145). At the temperature of 62° , which is that to which specific gravities are usually referred, a cubic inch of water weighs 252.458 grains; or at 60° , the cubic inch weighs almost exactly 252.5 grains, and the cubic foot 998.217 ounces *avoirdupois*, which is so near 1000, that the specific gravity of any substance, in reference to water, is very nearly the absolute weight of one cubic foot of such substance in *avoirdupois* ounces. The specific gravity of gold for instance, is 19.3, in reference to water as unity, and, therefore, a cubic foot of gold weighs *nearly* 19300 ounces. Water is about 815 times heavier than atmospheric air. Water at mean temperature is also assumed as the unit to which the specific heats of bodies, especially of solids and liquids, are usually referred: the specific heat of water has been ascertained with much precision by Regnault. (*Ann. Ch. et Ph.*, LXXIII. 35.)

Water is susceptible of compression, as was originally shown by Canton. Perkins states that a pressure of 2000 atmospheres occasions a diminution of 1-12th its bulk (*Phil. Trans.*, 1820). This subject has been more recently examined into by Ørsted, whose results differ from those of Perkins: the estimate of the latter he thinks too great (*Edin. Jour. Science*, xii., 201). According to his experiments and those of Colladon and Sturm (*Ann. de Chim. et Phys.*, xxxvi., 140), its absolute diminution of bulk for each atmosphere is 51.3-millionths of its volume. It is stated by Dessaignes that when water is submitted to very sudden compression, it becomes luminous. (THENARD, *Traité de Chimie*, i. 432.)

At the temperature of 32° water congeals into ice, which, if slowly formed, produces needles crossing each other at angles of 60° and 120° . Their forms are various, but the primitive figure has not been ascertained, though it is probably rhomboidal. The specific gravity of ice is 0.94, or thereabouts, varying a little in consequence of the air-bubbles which it includes: the densest ice, however, obtained by freezing-water deprived of air, is always lighter than water. Ice is a non-conductor of electricity, and under favourable circumstances becomes electric by friction. It is a very bad conductor of heat. In freezing, the water expands with such force as to burst very thick and strong vessels in which it is confined. The rupture of iron and leaden pipes is a familiar instance of this power. The most interesting experiments upon the subject are those of Major Williams (*Edin. Phil. Trans.*, vol. ii.) Bomb-shells, about 13 inches in diameter, and more than 2 inches thick, were filled with water; the fuse-holes were then plugged with iron-bolts, and, thus charged, were exposed to the open air at a temperature between -4° and -19° . At the moment of congelation the plugs were thrown out, and the ice protruded through the fuse-hole. When the plug was duly secured, the shell itself burst. The greatest difference observed in these experiments between the bulk of water before and after congelation was : 174 : 184. Exposed to the air, ice loses considerably in weight by evaporation. Hail is always crystallized in the form of two six-sided pyramids, applied base to base. The faces of the two pyramids meet at angles of about

80°, and one of the pyramids is always truncated. (SMITHSON, *Ann. of Phil.*, 2nd series, v. 340.)

If water be exposed to heat in open vessels it boils, or is converted into steam, at 212°, the barometer being at 30 inches; but the boiling-point of water varies considerably with the pressure (p. 173). The specific gravity of air being considered as = 1; that of *steam* is 0·624; 100 cubical inches weighing, at the temperature of 212°, and under mean pressure, 14·96 grains.

In the constitution of aqueous vapour or steam, *two* volumes of hydrogen and *one* of oxygen are condensed into *two* volumes, as in the annexed diagram. The specific gravity, therefore, of steam compared with that of hydrogen, is as 9 to 1: or in reference to air as = 1,

Hydrogen. 1	Oxygen. 8	=	Steam. 9
----------------	--------------	---	-------------

1 volume of hydrogen, specific gravity	0·0694
$\frac{1}{2}$.. oxygen,	0·5555

Specific gravity of steam therefore = 0·6249

At mean pressure, and at the temperature of 212°, the bulk of steam is 1689 times that of water. (See p. 172.)

Water enters into combination with a variety of substances, and is retained with various degrees of force: where it contributes to the regular form and transparency of crystallized bodies, it is termed *water of crystallization*. In other cases the compounds which water forms with substances are called *hydrates*, as with many of the metallic oxides; in both cases it may be considered as one of the constituents of the bodies, for it exists in them in a definite proportion.

Water, which has been exposed to the atmosphere, always contains a portion of air, as may be proved by boiling it, or by exposing it under the exhausted receiver of the air-pump. To separate the air, the water must be boiled for about two hours. It absorbs oxygen gas in preference to atmospheric air or nitrogen, and, when the air is expelled by boiling, the last portions contain more oxygen than those first given off. (HUMBOLDT and GAY LUSSAC, *Journal de Physique*, 1805.) It is by the oxygen thus dissolved in water that the blood of fishes is aerated, and as at great altitudes the quantity of the air in water is very small, in consequence of diminished pressure, it is found that fishes never thrive in alpine lakes.

Mr. Dalton states, that 100 cubical inches of spring water afford about two inches of air, which, after losing from 5 to 10 per cent. of carbonic acid by the action of lime-water, consists of 38 per cent. oxygen and 62 nitrogen (*New System*, 271). Dr. Henry obtained 4·76 cubic inches of gas from 100 of the water of a deep spring, of which 3·38 were carbonic acid gas, and 1·38 air, of the same standard as that of the atmosphere. There can, however, be no doubt, that the aeriform contents of different springs vary both in quantity and quality.

The following Table exhibits the quantity of different gases which water is capable of absorbing at mean temperature and pressure, the water being previously deprived of all aeriform matter by long boiling.

GASES.	100 Volumes of Water absorb	AUTHORITY.
Oxygen	3·7 volumes	Dalton.
Chlorine	200	Gay Lussac.
Oxide of Chlorine	800	Stadion.
Hydrogen	1·56	Henry.
Hydrochloric acid	50000 average	Davy.
Hydriodic acid		
Nitrogen	1·56	Henry.
Nitrous oxide	100	Ditto
Nitric oxide	5	
Nitrous acid		
Ammonia	67000 average	
Sulphurous acid	3000	Davy.
Sulphuretted hydrogen	100	Dalton.
Hydroguret of phosphorus	2·14	Henry.
Bi-hydroguret of phosphorus	12	Davy.
Carbonic oxide	2 average	
Carbonic acid	100	Dalton.
Carburetted hydrogen	12·5	Dalton.
Cyanogen	450	Gay Lussac.
Fluoboric acid	70000	John Davy.
Fluosilicic acid	35000	Saussure.
Hydroselenic acid	300	Berzelius.

The great importance of water as a natural and artificial agent, both mechanical and chemical, must be sufficiently obvious. The manner in which its changes of state or form influence the temperature of the globe, will be evident by a reference to the details given in the section on heat. When it freezes, the expansion which it suffers, and the force with which its particles arrange themselves in the crystalline form, are often actively concerned in the disintegration and decay of rocks and strata, and in the production of soils. Water is a most general and useful solvent, especially of saline bodies, the relative solubilities of which will be stated under their individual chemical history. Considered as a chemical agent, it is frequently resolved into its elements; these are sometimes respectively concerned in the production of new compounds: when chloride of phosphorus, for instance, acts upon water, its chlorine combines with the hydrogen of the water to form hydrochloric acid, and the phosphorus and oxygen unite to form phosphoric acid. In other cases bodies decompose water by the absorption of oxygen only, and the hydrogen is liberated in the gaseous form; but there is no instance in which the hydrogen is absorbed, so as to cause the evolution of gaseous oxygen.

PEROXIDE OF HYDROGEN.—OXYGENATED WATER. ($\text{h} + 2\text{o}$) or H_2O_2 . This singular compound was discovered by Thenard, in 1818: he obtained it by dissolving the *peroxide of barium* in hydrochloric acid and water, and adding sulphuric acid, by which the *protoxide* of barium is precipitated in the state of sulphate, and the excess of oxygen transferred to the water: by several repetitions of this process the water is gradually saturated with oxygen. There are so many difficulties attending the whole process, that it has been seldom repeated, and we know little of the nature of this extraordinary compound, except through the original essays of its discoverer: it has been surmised, from its properties, and

mode of formation, that it may be an aqueous solution of liquid oxygen; Thenard, however, regards it as a definite combination of hydrogen and oxygen, in which one atom of the former is combined with two of the latter, as follows:—

				Thenard.	Volumes.
Hydrogen 1 1 5.9 6.02 1
Oxygen 2 16 94.1 93.98 1
Peroxide of Hydrogen	1	17	100.0	100.00	

Much of the success of the process for obtaining this compound depends upon the purity of the peroxide of barium: the following details are from Thenard's memoir, (*Ann. de Chim. et Phys.*, viii. ix. x. and L.; THENARD'S *Traité de Chim.*, Ed. 4, ii., p. 41.)

To obtain pure peroxide of barium, prepare a pure nitrate of baryta, and give it a strong heat in a porcelain vessel, by which, baryta, not quite pure, but containing traces of silica and alumina but no manganese, will be obtained; the latter impurity must always be most cautiously avoided, for oxide of manganese possesses the property of energetically decomposing the oxygenated water. The baryta, broken into small pieces, is then introduced into a luted glass tube (the glass should not contain lead) large enough to contain about two pounds of it, and being heated to dull redness, a current of dry and perfectly pure oxygen gas is passed through it, which it rapidly absorbs; this operation is to be continued till the oxygen escapes from a small tube inserted into the opposite extremity of the larger one. The *peroxide of barium* thus obtained is pale gray, and frequently some pieces are speckled with green, which announces the presence of manganese, and which should be rejected: its distinctive character is, that it crumbles when a few drops of water are added to it, without producing heat.

The process then proceeds as follows. Take a certain quantity of water (about eight ounces for instance), and add to it a sufficiency of pure and fuming hydrochloric acid to dissolve about 230 grains of baryta: put this acid liquor into a glass vessel, which, during the operation, must be surrounded by ice: then take about 185 grains of the peroxide, rub it into a fine paste with a little water in an agate mortar, and put it into the acid liquor with a box-wood spatula; it soon dissolves without effervescence: to this solution add pure sulphuric acid, drop by drop, stirring it with a glass rod, till it is in slight excess, which is known by the readiness with which the sulphate of baryta falls: then dissolve a second portion of the peroxide and precipitate as before, taking care to use enough, but not too much, sulphuric acid. The liquor is now to be filtered, and the residue washed with a little water, so as to keep up the original measure by adding it to the first portion: a second and third washing of the residue with very small quantities of water may be advisable, and these liquors should be kept apart for the purpose of washing the filters in subsequent operations.

A fresh portion of the peroxide is then dissolved in the filtrated liquor and decomposed as before, filtering at every two operations, and washing the filter with the savings of the others; we thus proceed till the water is sufficiently oxygenated. When about two pounds of the

peroxide have been consumed, the water will be united to about thirty times its volume of oxygen, which is as much as it will retain, unless some hydrochloric acid be added, in which case M. Thenard has made it retain 125 volumes.

When the water is sufficiently oxygenated, it is retained in the ice, and supersaturated with the peroxide of barium, which occasions the separation of flocculi of silica and alumina, coloured with a little oxide of iron and of manganese; the whole is then filtered as quickly as possible, and returned into the vessel surrounded by ice; the baryta is separated by sulphuric acid; and pure sulphate of silver is added, to separate the hydrochloric acid, upon which the liquid, before milky, becomes suddenly clear. The sulphuric acid is ultimately separated by baryta, the liquor filtered, and placed in a shallow vessel, under the air-pump receiver, including a basin of sulphuric acid; the receiver being exhausted, the water evaporates and is absorbed by the acid, while the *peroxide of hydrogen*, being less vaporisable, remains: if it give out any oxygen, which sometimes happens, from its containing impurities, a drop or two of weak sulphuric acid will prevent its further evolution.

The peroxide of hydrogen thus concentrated has the following properties: its specific gravity is 1.45; it is colourless and inodorous; it blisters the cuticle of the tongue, and has a peculiar metallic taste. It does not congeal when exposed to cold, unless diluted. It is rapidly decomposed at a heat below 212° , and very slowly at ordinary temperatures; it may be long kept at 32° . It is decomposed by the voltaic pile with the same phenomena as water. It is decomposed by all metals except iron, tin, antimony, and tellurium: the metals should be finely divided, or in powder: silver and oxide of silver decompose it very suddenly with the evolution of heat and light: platinum and gold produce the same phenomena; lead and mercury slowly separate the oxygen. Orpiment and powdered sulphuret of molybdenum act upon it with the same violence as silver; the peroxides of manganese and of lead also occasion its instant decomposition.

HYDROGEN AND CHLORINE. HYDROCHLORIC ACID. MURIATIC ACID. CHLORHYDRIC ACID* ($h + c$) or hc' , or H Cl.—When equal volumes of hydrogen and chlorine are mixed, and exposed to light, they slowly combine, and produce *hydrochloric acid gas*. If the above mixture be exposed to the direct solar rays, a detonation often ensues, as was first remarked by Gay Lussac and Thenard.—(*Recherches Physico-Chymiques*, ii. 129.) It also detonates when suddenly exposed to the intense light

* This is a *hydrogen-acid*, or *hydracid*, of which there are several; some with simple, others with compound bases; chlorine, iodine, bromine, and fluorine, form with hydrogen acids analogous to the hydrochloric, and these constitute an important and well-defined group; sulphur, selenium, arsenic, tellurium, phosphorus, and a few other substances, form a second group; and a third includes the hydracids with compound

bases, such as the hydrocyanic, &c. The hydracids do not combine with basic oxides to produce salts, but when they act on such oxides, a mutual decomposition of the oxide and of the acid ensues: thus when soda or oxide of sodium is added to hydrochloric acid, the sodium of the base and the chlorine of the acid unite to form chloride of sodium, and the oxygen of the base and the hydrogen of the acid form water.

of the voltaic discharge passing between charcoal points. That direct solar light is not necessary to effect this combination has been shown by Professor Silliman (*American Journal of Science*, iii. 342), who relates a case of the explosion of the mixed gases in dull and cloudy daylight. This fact furnishes a caution against mixing any considerable quantities of chlorine and hydrogen. According to Dr. Henry, the agency of light on these gases may be beautifully shown by filling a tube, about half an inch diameter, and twelve inches long, with the mixed gases, and alternately shading it with an opaque cover, and exposing it to the sun's rays. The moment the tube is exposed even to the diffused light of day, a cloudiness will appear within it, and the water will ascend more or less rapidly according to the intensity of the light. The effect even of a passing cloud is distinctly seen in retarding the rapidity of the combination, which is very striking in the full solar light.—(*Elements*, vol. i.) Seebeck states that the mixed gases, exposed to the sun's rays in a tube of violet-coloured glass, combine rapidly, but without explosion, and that in a tube of red glass they scarcely act upon each other.

The best mode of showing the composition of hydrochloric acid, is to introduce into a small but strong glass vessel a mixture of the two gases, and to inflame them by the electric spark; no change of volume ensues, and muriatic gas results. The apparatus shown at fig. 230, may be used for this purpose; or a jet of hydrogen may be inflamed and introduced into a jar of chlorine; during its combustion the yellow colour of the chlorine disappears, and hydrochloric acid is formed.

Sir H. Davy found that the heat evolved during the combustion of a mixture of equal volumes of chlorine and hydrogen exceeded that produced by a mixture of oxygen and hydrogen, and that the former mixture was inflamed at a lower temperature, and would bear much greater rarefaction than the latter, without losing its explosive property. Oxygen and hydrogen ceased to explode when rarefied 18 times, but chlorine and hydrogen retain their combustibility when rarefied 24 times.

By passing a succession of electric sparks through hydrochloric acid gas Dr. Henry effected its partial decomposition, and when it had gone to a certain extent, the gases again combined: he also found, that by passing a mixture of oxygen and hydrochloric acid gas through a red hot porcelain tube, or by the transmission of electric sparks, water was formed and chlorine evolved. At the temperature of 250° , the same change was produced upon the mixture by spongy platinum.—(*Phil. Trans.*, 1812 and 1824.)

Hydrochloric acid gas may also be decomposed by the action of several of the metals.—(DAVY, *Phil. Trans.*, 1810.) Potassium, for instance, absorbs the chlorine, and the hydrogen is evolved. This experiment is best made by introducing a piece of potassium into a small retort, which is then to be exhausted and filled with hydrochloric acid gas from a jar standing over mercury. The potassium generally takes fire, but is sometimes prevented burning by the formation of a film of chloride of potassium, and then requires to be heated, which, however, should be done carefully, as the retort is apt to break in consequence of the intensity of the combustion that ensues. When it has cooled it will be found that the residuary gas is *hydrogen*, equal to half the original bulk of the

hydrochloric acid. If a piece of burning potassium be introduced in a small copper spoon, into a bottle filled with hydrochloric acid gas, the metal continues in vivid combustion, and the evolved hydrogen at the same time takes fire, and burns with flame at the neck of the bottle. Tin and lead heated in the gas also effect its decomposition, and

Hydrogen.	Chlorine.	=	Hydrochloric Acid.
1	36		37

evolve exactly half its bulk of hydrogen. The specific gravity of hydrogen to chlorine is as 1 to 36; one volume of hydrogen and one

of chlorine combine to form two volumes of hydrochloric acid gas, as shown in the above diagram; or (according to Davy, and to Gay Lussac and Thenard), hydrochloric acid gas consists of

					Volumes.

The greater number of metallic oxides when heated in gaseous hydrochloric acid, decompose it; metallic *chlorides* are formed, and the oxygen of the oxide combining with the hydrogen of the acid forms water.

Hydrochloric acid gas was discovered by Priestley in 1772: it is generally procured for the purposes of experiment, either by applying heat to the strong liquid hydrochloric acid; or, more readily and in greater abundance, by acting upon common salt, or sal-ammoniac, by sulphuric acid; the evolved gas must be received over mercury. The salt should be put in fragments into a small tubulated retort, which may be one-fourth filled with it: the sulphuric acid should barely cover the pieces of salt; the gas is instantly extricated, and when its evolution slackens, it may be quickened by the gentle heat of a lamp. It is convenient to put a long strip of folded blotting-paper into the neck of the retort, which absorbs any liquid that may chance to go over, and prevents its soiling the mercury. With a little practical dexterity, clean and dry bottles may be conveniently filled with this gas in the way described in the note at page 366.

The specific gravity of hydrochloric acid gas compared with air is 1.269; and as it consists of equal volumes of hydrogen and chlorine (combined without change of volume), 100 cubical inches must weigh 39.36 grains; for

50 cubic inches of hydrogen	weigh	1.069
50 .. chlorine	..	38.299
<hr/>		<hr/>
100 .. hydrochloric acid gas	..	39.368

According to Thomson, 100 C. I. at 32° weigh 42.126 grains.

Although permanently gaseous at all common temperatures and pressures, Mr. Faraday liquified this gas by generating it in a sealed tube, so as to expose it to a pressure of about 40 atmospheres at 50°. It was colourless, and possessed a refractive power inferior to that of water.

Hydrochloric acid gas is perfectly unrespirable; it extinguishes the flame of a taper, and is itself unflammable. It irritates the skin. It

has a strong attraction for water: when it escapes into the air it forms visible fumes, arising from its combination with aerial vapour. A piece of ice let up into the gas over mercury, immediately liquifies and absorbs it: and if a tall jar of the gas be carefully transferred, with its mouth downwards, from the mercurial to the water-trough, the water instantly rushes in with violence, and fills it. Litmus-paper is powerfully reddened by this gas, and turmeric-paper receives from it a brown discoloration not unlike the effect of an alkali.

Water takes up 480 or 500 times its bulk of hydrochloric acid gas, and has its specific gravity increased from 1 to 1.210. This may be shown by throwing up a few drops of water into a tall jar of the gas standing over mercury; the gas disappears, and the mercury fills the vessel. There is considerable elevation of temperature during this condensation of the gas.

For saturating any quantity of water with gases which are easily soluble in that fluid, we generally employ *Woulfe's apparatus*, one form of which is shown in the annexed cut. *a* is a tubulated retort, in which

the materials producing the gas or vapour are contained; *b*, a receiver, communicating by a bent tube with the three-necked bottle *c*, which is connected also by a tube with *d*. These bottles are about half-filled with water, or any other fluid intended to be saturated with the gas; when that in *c* has become saturated, it passes into *d*, and afterwards through the tube *e*, which may be placed under the water, or mercury, in the pneumatic trough. In case absorption should take place in the vessels *a* or *b*, the pressure of the external air might force the water from *d* into *c*, and from *c* into the balloon *b*. This is prevented by the safety-tubes *f, f*, which, dipping not more than half an inch under the surface of the water, allow a little air to enter, so as to compensate for the absorption. The different joints may be secured either by grinding, or by well-cut corks rendered tight by a mixture of drying-oil and pipe-clay.

When gaseous hydrochloric acid is thus dissolved in water, it forms the *liquid hydrochloric acid*, commonly called *muratic acid*, or *spirit of salt*, which was discovered by Glauber about the middle of the seventeenth century. It is generally procured by distilling a mixture of dilute sulphuric acid and common salt. The proportions directed in the *London Pharmacopœia* are two pounds of salt, and 20 ounces of sulphuric acid, diluted with 12 ounces of water. The retort containing these ingredients may be luted on to a receiver, containing

the same quantity of water used in diluting the sulphuric acid, and the distillation carried on in a sand-bath. The specific gravity of the product is stated to be 1.160, and 100 grains of it should be saturated by 132 grains of crystallized carbonate of soda. The quantity of real acid in hydrochloric acid of different densities is best ascertained by the quantity of pure carbonate of lime (Carrara marble, for instance), which a given weight of the acid dissolves. Every 50 grains of the carbonate are equivalent to 37 of real acid.

In preparing this acid upon the large scale an apparatus of earthenware is sometimes used, similar to that described under the article *Nitric Acid*; the market, however, might easily be supplied with hydrochloric acid to any amount, were the demands adequate; for in the operations in which common salt is decomposed for the manufacture of carbonate of soda, enormous quantities of hydrochloric acid are thrown away.

When this acid is pure, it is perfectly colourless, but it generally has a yellow hue arising from particles of cork or lute that have accidentally fallen into it, or sometimes from a little iron. Dr. Thomson suggests that the pale yellow tint occasionally observed in this acid apparently pure, may possibly arise from a trace of bromine, derived from the salt. The acid of commerce almost always contains iron and sulphuric acid, and sometimes nitric and sulphurous acid. The iron may be detected by the black tint produced by tincture of galls, in the acid previously saturated by carbonate of soda. If a dilute solution of chloride of barium, dropped into the acid, occasion a white cloud or precipitate, it announces sulphuric acid. The presence of nitric acid (and of free chlorine and bromine?) is shown by boiling some gold-leaf in the suspected hydrochloric acid, and then dropping into it a solution of protochloride of tin, which, if nitric acid were present, produces a purplish tint, showing the gold to have been acted upon, which it is not by pure hydrochloric acid. Sulphurous acid is indicated by the addition of a few crystals of protochloride of tin, which, after standing, produces a brown precipitate, containing sulphur in combination with tin (GERARDIN). Saline substances may be detected by evaporating the acid to dryness: when pure, it leaves no residue.

The highly-concentrated liquid acid emits copious fumes when exposed to air: it boils at a temperature of about 112° *, and gives off the gaseous acid: it freezes at -60° . When mixed with water, it occasions a slight elevation of temperature. It is decomposed by many substances containing loosely-combined oxygen, such as chloric, iodic, and bromic acids, and several of the metallic peroxides. Its decomposition by peroxide of

* The variation of the boiling-point with the density of hydrochloric acid is shown in the following table by Dalton, from which it appears that it is highest when it contains between 19 and 20 per cent. of the gas: the strong acid becoming weaker, and the weak acid stronger by boiling.

manganese, for the production of gaseous chlorine, has already been referred to: in this case, oxygen is imparted by the oxide to the hydrogen of the acid, so as to form water, and the chlorine previously in combination with the hydrogen is liberated; at the same time a chloride of manganese is formed. In this case, 1 atom of peroxide of manganese, and 2 atoms of hydrochloric acid, give rise to the production of 2 atoms of water and 1 atom of chloride of manganese, 1 atom of chlorine being evolved. The elements which are employed are

1 atom Manganese . . = 28	2 atoms Hydrogen . . . = 2

1 atom Chlorine = 36.	

or, in symbols, $(man + 2o)$ and $2(h + c) = (man + c) 2(h + o)$ and c .

The decomposition of hydrochloric by nitric acid will be afterwards explained. When metallic zinc is put into strong liquid hydrochloric acid it is rapidly decomposed, and the *hydrogen* copiously evolved may be burned as it escapes: some peroxide of lead added to another portion of the acid immediately disengages *chlorine*, which may be shown by its bleaching power upon a piece of paper dipped in indigo blue: this experiment well illustrates the separation of the two elements of the acid. In the voltaic circuit its chlorine is evolved at the anode and its hydrogen at the cathode, so that when thus electrolysed, and tinged with indigo, a bleaching effect is produced at the anode (p. 311).

Uncombined hydrochloric acid exists in small quantity in the human gastric juice; it is not found in nature except as an occasional volcanic product. The principal uses of this acid are as a medicine, and in some of the arts, where it is chiefly employed as a solvent of metals. It has been used in the gaseous state as a disinfectant, but is more annoying, and less efficient than chlorine; indeed, by some, its disinfecting powers have been altogether denied. It is extremely injurious to vegetation: mixed with 20,000 times its volume of atmospheric air it proves fatal to plants, shrivelling and killing all the leaves in twenty-four hours. (CHRISTISON and TURNER.)

The following tables by Mr. E. Davy and by Dr. Thomson show the value and atomic composition of hydrochloric acid of different densities: Dr. Ure, in his *Dictionary*, has also published a valuable and extended table upon the same subject; the data upon which it is formed and several important facts connected with this subject, will be found in his paper relating to it in the *Quarterly Journal of Science* (xii. 286).

It appears from Dr. Thomson's table that the strongest liquid hydrochloric acid contains 1 atom of real acid + 6 atoms of water; when this is evaporated in the air, acid escapes, and it comes, according to Graham, to contain 1 atom of acid + 12 of water; according to Dr. Clark, the acid which is unaltered by distillation contains about 16 atoms of water.

HYDROGEN AND IODINE; HYDRIODIC ACID. ($h+i$) or hi or $H\ I$.—This compound of hydrogen and iodine was first examined by Davy and Gay Lussac. (*Phil. Trans.*, 1814. *Ann. de Chim.*, xci.) It cannot be obtained by the action of sulphuric acid upon iodide of sodium or potassium, because the hydriodic and sulphuric acids partially decompose each other, evolving iodine, and forming sulphurous acid and water. Hydriodic acid may be formed by the direct union of its elements, as by passing a mixture of hydrogen and the vapour of iodine through a red-hot tube; but it is most easily procured by the mutual action of water, phosphorus, and iodine; or, what amounts to the same thing, by the action of iodide of phosphorus on water. In thus procuring it, it is convenient to use a retort tube, into the bulb of which is introduced the moist iodine, and a small stick of phosphorus, about a tenth part of the weight of the iodine, placed in the neck above it, which can be shaken down upon the iodine when the beak of the tube or retort is placed under the inverted jar; a quantity of the gas is instantly generated, and a further portion is obtained on applying the flame of a spirit-lamp. In this case decomposition of the water and of the iodide ensue, and phosphorus and hydriodic acids are the results. Upon the same principle it may be obtained by previously preparing iodide of phosphorus, and gently heating it with a little water: if too high a temperature be used, phosphuretted hydrogen is also given off.

According to D'Arcet, hydriodic acid gas may be obtained very pure by the following process:—Hydrophosphoros acid is to be evaporated

until upon the point of evolving phosphuretted hydrogen gas. It is then to be put, with its weight of iodine, into a small tube retort; the gas is liberated, upon applying a gentle heat: 100 grains of the acid, and 100 of iodine, afforded 120 cubical inches. The residue of the operation is a mixture of phosphoric acid, and of the compound of hydriodic acid and phosphuretted hydrogen. (*Ann. de Ch. et Ph.*, xxxvii. 220.)

Whichever process is followed, if the gas be received over mercury it should be transferred as fast as possible into an exhausted vessel, as it is otherwise soon decomposed. It may often be conveniently collected in dry phials, without a mercurial trough, by its density, as in the methods described in the note to p. 230.

Hydriodic acid is colourless, sour, exhales fumes in the air, and smells like hydrochloric acid. It strongly reddens vegetable blues. Its specific gravity compared with air is as 4.38 to 1; 100 cubic inches weighing about 136 grains (or 142.4 grains at the temperature of 32°. THOMSON). Compared with hydrogen its specific gravity is as 63.5 to 1. It is not permanent at a red heat, for when passed through a red hot porcelain tube it is partially resolved into iodine and hydrogen.

Hydriodic gas is rapidly and abundantly absorbed by water, but in what exact proportion has not been determined. The solution, exposed to a temperature below 260°, becomes concentrated by loss of water; at about 260° it boils, and may be distilled. The specific gravity of the strongest liquid acid is 1.7. It becomes dark-coloured when kept in contact with air, in consequence of a partial decomposition, and it readily dissolves iodine, becoming of a deep brown colour. It is decomposed by chlorine and by nitric and sulphuric acids.

The *liquid hydriodic acid* is best prepared by passing sulphuretted hydrogen through a mixture of iodine and water: sulphur is deposited, and on heating and filtering the liquor, a pure solution of hydriodic acid is obtained, which may be concentrated by evaporation. It may also be obtained by heating iodine, phosphorus, and water: or by passing sulphuretted hydrogen through a solution of 1 part of iodine in 16 of alcohol, filtering, diluting with 32 of water, and subsequent distillation to drive off the alcohol and excess of sulphuretted hydrogen.

When hydriodic acid gas is mixed with oxygen, and passed through a red-hot tube, it is resolved into iodine and water. Its decomposition by chlorine produces hydrochloric acid, sometimes with explosion, and the blue vapour of iodine is rendered evident, but presently disappears in consequence of the formation of chloride of iodine. This decomposition is beautifully shown by suffering hydriodic acid gas to pass into a jar of atmospheric air, mixed with about a twelfth its bulk of chlorine; the violet fumes are then more permanent. A little strong nitric acid dropped into hydriodic acid gas energetically decomposes it, with the evolution of so much heat that the gas is occasionally inflamed. (TURNER.)

The experiments of Gay Lussac have proved the composition of hydriodic acid gas to be analogous to that of the hydrochloric: namely, that it consists of 1 volume of the vapour of iodine, and 1 of hydrogen: these produce 2 volumes of the acid. By the action, for instance, of mercury and some other metals, hydriodic acid gas is decomposed, the iodine being absorbed by the metal, and evolving from 2 volumes of the

gas, 1 of hydrogen: so that the annexed diagram represents its composition. That such is the composition of this acid is also shown by its weight, for,

Hydrogen	Iodine.	Hydriodic Acid.
1	126	127

	50 cubic inches of hydrogen weigh	50 " " iodine vapour	100 " " hydriodic gas	Gras.
				1.06
				134.92
				135.98

Or, it consists of

	Hydrogen	Iodine	Hydriodic acid	Volumes.	Sp. Gr.
	1	126	1	0.8	0.069
	1	126	1	99.2	8.700
	1	127	100.0	2	4.384

Hydriodic acid dissolves iodine; so likewise do the solutions of iodide of potassium and of zinc; taking up a quantity of iodine equal to that which they already contain: these compounds have been termed *ioduretted iodides*, and are by some considered as containing a peculiar acid which may be termed *hydriodous* acid, composed of 1 atom of hydrogen = 1 + 2 of iodine = $126 \times 2 = 252$.

The hydriodic acid is not found uncombined in nature; some of its combinations have already been mentioned under the head of *iodine*. Its presence may be detected by mixing a cold solution of starch with the liquid suspected to contain it, and then adding a few drops of a solution of chlorine or of nitric or sulphuric acid: this liberates iodine, and produces a blue tint.

HYDROGEN AND BROMINE. HYDROBROMIC ACID. ($h+b$) or hb' or HBr . Bromine and hydrogen do not act upon each other, even under the influence of the sun's rays, at common temperatures; but when bromine, phosphorus, and water, are brought into contact, a decomposition ensues analogous to that described under the article *hydriodic acid*; and *hydrobromic gas* is generated, which may be collected over mercury, or in dry phials. Hydrobromic gas may also be obtained by acting upon a mixture of bromine vapour and hydrogen by a coil of red-hot platinum wire: and it is evolved when bromide of potassium is decomposed by sulphuric acid, but in this case a portion of it is apt to be decomposed.

This gas is colourless, sour, of a pungent and highly-irritating odour, and yields dense vapours when mixed with humid air. It undergoes no change when passed through a red-hot tube, either alone or mixed with oxygen or iodine; but chlorine decomposes it, producing vapour and drops of bromine, which, being absorbed by mercury, leaves hydrochloric acid. We learn, therefore, that the attraction of bromine for hydrogen exceeds that of iodine, but is inferior to that of chlorine. The attraction of oxygen, and of bromine for hydrogen, is probably nearly equal; for bromine does not decompose water, nor does oxygen decompose hydrobromic acid. Hydrobromic gas is not altered by mercury, but tin and potassium entirely decompose it; the former requires the aid of heat;

but potassium acts at common temperatures, diminishing the gas to half its bulk, and becoming converted into a bromide of potassium. Hence it appears that the constitution of hydrobromic acid is analogous to hydrochloric and hydriodic acids, and that it consists of equal volumes of hydrogen and bromine vapour. The weight therefore of 100 cubic inches of hydrobromic acid will be as follows:—

Hydrogen.	Bromine.		Hydrobromic Acid.
1	78	=	79

50 cubic inches of hydrogen weigh	1.06	Grs.
50 " " bromine vapour	84.00	
100 " " hydrobromic gas	85.06	

Or, it consists of

			Volumes.	Sp. Gr.
Hydrogen	1 . . . 1 . . .	1.266 . . . 1 . . .	1 . . .	0.069
Bromine	1 . . . 78 . . .	98.734 . . . 1 . . .	1 . . .	5.400
Hydrobromic acid 1	79	100.000	2	2.734

Hydrobromic acid gas is rapidly absorbed by water; heat is evolved, and a fuming liquid acid obtained, which is colourless when pure, but which readily dissolves bromine, and acquires a yellow colour. This acid may also be obtained by the action of sulphuretted hydrogen on bromine and water. It is instantly decomposed and discoloured by chlorine. Nitric acid also decomposes it, producing the evolution of bromine, and the formation of water and nitrous acid. This mixture dissolves gold. Hydrobromic acid is not readily decomposed by sulphuric acid; but on decomposing bromide of potassium by sulphuric acid, a little sulphurous acid is generally formed.

HYDROGEN and FLUORINE—HYDROFLUORIC ACID. ($h+f$) or hf or HF. This acid was made known by Scheele: the process for procuring it pure was first suggested by Mr. Knight (*Phil. Mag.*, xvii. 357.) Its properties were examined by Gay Lussac and Thenard in 1810. (*Recherches Physico-chimiques*.) When finely-powdered *fluoride of calcium*, or *fluor spar*, as it is usually called, (carefully selected for its purity,) is distilled with twice its weight of sulphuric acid, a highly volatile and corrosive liquid, which is *hydrofluoric acid*, is obtained; it acts powerfully on glass and most of the metals: the retort employed in the experiment may be of lead, with a tube and receiver of pure silver; the receiver must be immersed in a mixture of ice and salt. The product is best preserved in a silver bottle, with a well-fitted stopper of the same material. When pure, it is clear, colourless, very volatile, and smokes when exposed to air: at temperatures above 60° it flies off in vapour. Its specific gravity is 1.0609; but by the gradual addition of a certain proportion of water it acquires a considerable increase of density, the mixture having a specific gravity of 1.25. Its attraction for water exceeds that of sulphuric acid; and when dropped into water it excites a hissing noise, and great heat is evolved. Its vapour is dangerously pungent and irritating, and the liquid acid eminently active upon organic substances; a minute drop of it upon the skin produces a painful sore, and in larger quantities danger-

ous and malignant ulceration: hence the vessels containing it require to be handled with great caution. Its most characteristic property is the energy with which it acts upon glass: its vapours soon destroy the polish and transparency of all neighbouring glass vessels, and when dropped upon glass, great heat and effervescence are produced, and dense fumes evolved, consisting of *fluosilicic acid*. Diluted with about six parts of water, the acid may be used for *etching upon glass*, which it effectually accomplishes in a few minutes.

The nature of this powerful and peculiar acid is as yet imperfectly understood, its basis, *fluorine*, not having been obtained in an insulated form. All analogy, however, leads us to regard it as a compound of fluorine and hydrogen. In the voltaic circuit hydrogen is evolved from it at the negative electrode, and the positive platinum wire corroded and converted into a brown compound, probably of fluorine and platinum. Many of the metals also decompose it with the evolution of hydrogen; and peculiar compounds result, *fluorides*, consisting of the metal in combination with fluorine. The action of potassium upon this acid is very energetic; it is attended by explosion, by the liberation of hydrogen, and by the formation of a peculiar soluble saline compound, which is considered as a *fluoride of potassium*. Kuhlman's experiments are also quite consistent with these views: he found that pure fluor spar (fluoride of calcium) was not in the least acted upon, even at a red-heat, by anhydrous sulphuric acid; and that when hydrochloric acid was transmitted over fluor spar at a red heat hydrofluoric acid was disengaged and chloride of calcium formed. It cannot therefore be doubted that hydrofluoric acid, as originally suggested by Davy, is analogous to the other hydracids (*Phil. Trans.*, 1813, p. 263):

that it may therefore be regarded as composed of equal volumes of hydrogen and fluorine combined, without condensation. 100 cubic inches of its vapour would therefore weigh 20·2 grains, for,

Hydrogen.	Fluorine.		Hydrofluoric Acid.
1	18	=	19

50 cubic inches of hydrogen	. .	=	1·06
50 " " fluorine	. .	=	19·14
100			hydrofluoric acid = 20·20

Hence, therefore, its atomic constitution is

§ VII. NITROGEN.

NITROGEN, or *Azote* was first recognised as a distinct aëriform fluid by Dr. Rutherford in 1772. (Thesis, *De Aëre Mephitico*.) Dr. Priestley called it *phlogisticated air*.

Nitrogen may be obtained by burning phosphorus in a confined portion of atmospheric air. For this purpose a tall glass jar should be selected,

open at bottom, and stopped at the top: a small Wedgwood basin containing a sufficiency of inflamed phosphorus is then set afloat in the water-trough, and the jar, without its stopper, immediately inverted over it. A quantity of air is at first expelled by the heat: the stopper is then replaced, and the combustion goes on for some time; when it has ceased, and the apparatus has cooled, the basin is easily removed by agitating the jar, so as to sink it through the water; the residuary gas is then thoroughly washed with lime water, and is nitrogen nearly pure.

Another mode of obtaining nitrogen, which furnishes it in a state of considerably purity, consists in passing chlorine into a strong aqueous solution of ammonia. This may be done by nearly filling a Wolfe's bottle with two necks with the solution, and passing gaseous chlorine into it from a retort containing hydrochloric acid and oxide of manganese; a bent tube issuing from the other neck passes under the shelf of the pneumatic apparatus, and through it the nitrogen escapes, and may be collected; but care should be taken to leave excess of ammonia in the bottle. In this experiment ammonia, consisting of hydrogen and nitrogen (see AMMONIA), is decomposed by the chlorine, which unites with its hydrogen to form hydrochloric acid, and gaseous nitrogen is evolved: a solution of hydrochlorate of ammonia is at the same time obtained, and if excess of chlorine be used, chloride of nitrogen, a dangerously explosive compound, may be formed. If the ammoniacal solution be very concentrated, the bubbles of chlorine often produce flashes of light and slight explosions: these are harmless, and may be prevented by dilution of the ammonia. The following is the disposition of the apparatus: *a* is the retort and tubulated receiver containing the materials for the evolution of chlorine; *b* the two-necked bottle about three-fourths filled with strong liquid ammonia; *c* a bent tube, carrying the evolved nitrogen into the water-trough, where it is collected in the inverted jar *d*.

According to Berzelius, the purest nitrogen is obtained by filling a bottle about one-third full of a liquid amalgam of lead and mercury, carefully stopping it, and agitating it with the included air for two hours or more; the highly-divided lead absorbs the oxygen, and leaves pure nitrogen. On opening the bottle under water, the liquid rushes in, and demonstrates the degree of absorption.

If equal weights of iron-filings and sulphur be made into a paste with

water, and exposed to a confined portion of atmospheric air, it will, in the course of forty-eight hours, absorb the oxygen, and leave the nitrogen nearly pure.

There are many other processes by which nitrogen may be obtained, some of which will be further noticed under the article *Atmospheric Air*. It is also frequently evolved during the decomposition of animal matter. If lean muscular flesh, for instance, be heated in nitric acid diluted with ten or twelve parts of water, this gas is given off, though not pure: these cases of its evolution will be more particularly explained afterwards. When nitrogen gas is required deprived of moisture, it may be dried by exposure to fragments of quicklime, or of fused chloride of calcium.

Nitrogen is a permanently elastic colourless gas, with neither smell nor taste, having no action upon vegetable colours or upon lime-water; neither is it absorbed by water, except that fluid has been deprived of its ordinary portion of air by long boiling, when it takes up about one and a half *per cent.* Its refractive power in regard to light is to that of atmospheric air as 1.0340 to 1.0000. It is rather lighter than atmospheric air, compared with which its specific gravity is 0.972: 100 cubic inches weigh at mean temperature and pressure 30.16 grains. At 32° the weight of 100 cubic inches is 31.879 grains. (THOMSON.) Its specific gravity in reference to hydrogen is as 14 to 1.

An animal immersed in nitrogen is instantly suffocated, whence it was called by Lavoisier *azote* (from *a*, *privative*, and *ζωή*, life): but if that term be taken in its strict sense, all gaseous bodies (excepting atmospheric air) might be included under it; for even oxygen itself will not indefinitely support life: moreover, nitrogen, as it exists in the atmosphere, mixed with oxygen, appears to be absolutely essential to animal life; for no other gas can be substituted for it. Its influence in *respiration*, as a component of atmospheric air, will be considered afterwards. It is contained in almost every form of animal matter. If we consider the term *nitrogen* as merely implying that it is a component of nitric acid, it is explicit and unobjectionable; I, therefore, adopt it in preference to that of *azote*.

Nitrogen is, in the strictest sense of the word, a non-supporter of combustion; for all burning bodies are immediately and perfectly extinguished by it: this is the case with the flame of a taper, with phosphorus in intense combustion, and even with potassium, which, however highly heated, shows no inclination to burn in pure nitrogen.

The electro-chemical relations of nitrogen are still obscure, and whether it is or is not an ion has not been determined. How far it deserves to be called an *inflammable substance* is not obvious: its attraction for oxygen is not powerful, and the two bodies when mixed in their gaseous state show no tendency to combine; they do, however, unite in several proportions; but their compounds are formed at low temperatures; or the nitrogen and oxygen are presented to each other in their *nascent states*, that is, before one or both of them have acquired the independent gaseous form. The same remark applies to all compounds of this gas.

Under certain circumstances, however, nitrogen may be made to undergo a kind of combustion, as when electric sparks are passed through atmospheric air, or through a mixture of one volume of nitrogen with

two or three of oxygen; in this case each spark will be attended by the production of a trace of nitric acid, and after some hundred sparks, the blue of litmus will be changed to red (p. 325). Here combustion appears to take place in that portion of the gas immediately subject to the action of the sparks; but the temperature of the surrounding gas is not thus sufficiently elevated to enable the combustion to spread beyond the immediate sparks. Berzelius has well compared this action to that which ensues when sparks are passed through a mixture of hydrogen and a large relative quantity of atmospheric air or of oxygen; in that case no general combustion of the mixture is effected; but water is slowly formed by the action of each successive spark upon the portion of the gaseous mixture immediately subjected to its heating influence; and it is probable that the electric spark made to act upon mixtures of nitrogen and oxygen under considerable pressure might be more effective in inducing combination; but few of the nitric compounds are stable, or capable of sustaining a continued red heat without decomposition.

If a mixture of nitrogen with twelve or fourteen volumes of hydrogen be set fire to as it issues from a small tube, and burned either in common air or in an atmosphere of oxygen, water and nitric acid will be formed; so that in this case the nitrogen may be said to undergo combustion by the aid of the elevated temperature of the flame of hydrogen; but it must be recollected that in these cases nitric acid could not be produced without the presence of water, and that it may tend to dispose an union which would not otherwise take place. The formation of a trace of nitric acid when hydrogen is burned in common air is referable to the same cause.

Much discussion has arisen respecting the nature of nitrogen; and the question has been agitated, whether it is or is not a *simple body*; but although many ingenious surmises have been published on the subject, and many analogies suggested in favour of its compound nature, no experimental proofs have been hitherto adduced: Sir H. Davy (*Elements of Chem. Philos.*, 474) and Berzelius have each discussed this question, chiefly in reference to the phenomena of the supposed *metallisation of ammonia* (see MERCURY); and the latter has proposed the name *nitricum* for the imaginary base of nitrogen, assuming that gas to be a suboxide. (*Lehrbuch*, i. 208.) He has also adverted to the apparent formation of nitrogen by graminivorous animals, but this question will more properly be considered when upon animal products.

NITROGEN AND OXYGEN.—These bodies unite in *five proportions*, and form the compounds called,

1. Nitrous oxide	($n + 0$)
2. Nitric oxide	($n + 20$)
3. Hyponitrous acid	($n + 30$)
4. Nitrous acid	($n + 40$)
5. Nitric acid	($n + 50$)

PROTOXIDE OF NITROGEN. NITROUS OXIDE ($n + 0$) NO, or $\dot{\text{N}}$, was discovered by Dr. Priestley, in the year 1776; he called it *dephlogisticated nitrous air*: it has also been called *gaseous oxide of azote*. It may be formed by exposing *nitric oxide* ($n + 20$) to the action of iron-filings,

or of a mixture of sulphur and iron-filings, by which one equivalent of its oxygen is absorbed, and the remaining elements left in such proportions as to constitute nitrous oxide. But the gas thus procured is not pure. It is most easily and abundantly obtained in a state of purity by heating *nitrate of ammonia* in a glass retort over an Argand lamp, to a temperature of about 420° . The gas which passes off, provided the salt be pure, and the temperature not too high, may be collected over warm water, and is pure *nitrous oxide*. If the nitrate of ammonia contain a mixture of the hydrochlorate, the gas will be contaminated by chlorine; and if too much heat be used in the decomposition of the pure salt (which may be known by white vapours appearing in the retort) it will contain nitric oxide. The salt should be kept in a state of gentle ebullition, so as to maintain a quick but not violent evolution of gas.

The presence of *chlorine* in nitrous oxide is ascertained by its smell, and may be avoided by using pure nitrate of ammonia, the solution of which should not be rendered turbid by nitrate of silver. *Nitric oxide* is detected in it by the appearance of red fumes on mixing the gas with oxygen: it may be abstracted by agitating it with a solution of *protosulphate of iron*, which has no action upon nitrous oxide, but absorbs the nitric oxide, and acquires a deep olive colour. If nitrous oxide be mixed with *oxygen* or with *common air*, it affords red fumes upon adding to it a few bubbles of nitric oxide, and it is not, as it ought to be, entirely absorbed when agitated with thrice its bulk of cold water.

100 cubic inches of nitrous oxide weigh 47.220 grains; its specific gravity, therefore, to hydrogen, is as 22 to 1; and to atmospheric air as 1.524 to 1000. At the temperature of 32° , 100 cubic inches weigh 49.978 grains. (THOMSON.) Its taste is sweet, and its smell peculiar, but agreeable. It is absorbed when agitated with water, which takes up about its own bulk, and evolves it unchanged when heated; it should, therefore, be collected and preserved in stopped bottles.

Nitrous oxide was generally considered not only as unrespirable, but as eminently noxious; the attempts, however, that had been made to breathe it, were with an impure gas: when obtained perfectly pure, Sir H. Davy found that it might be breathed when mixed with common air, without any injurious effects, and he afterwards ventured upon its respiration in a pure state, and discovered its singular effects upon the system, which in many respects resemble those of intoxication. (*Researches Chemical and Philosophical, chiefly concerning Nitrous Oxide*. London, 1800.) The experiment of breathing this gas, however, cannot be made with impunity, especially by those who are liable to a determination of blood to the head. The following accounts will serve to give a general idea of its singular powers. They are quoted from Sir H. DAVY'S *Researches*, in which many important details concerning the effects of different gaseous bodies upon the system will be found. The first account is by Mr. Tobin, and the second by Dr. Roget:—

“On the 29th of April I breathed four quarts from and into a silk bag. The pleasant feelings produced at first, urged me to continue the inspiration with great eagerness. These feelings, however, went off towards the end of the experiment, and no other effects followed. The gas had probably been breathed too long, as it would not support flame.

I then proposed to Mr. Davy, to inhale the air by the mouth from one bag, and to expire it from the nose into another. This method was pursued with less than three quarts, but the effects were so powerful as to oblige me to take in a little common air occasionally. I soon found my nervous system agitated by the highest sensations of pleasure, which are difficult of description; my muscular powers were very much increased, and I went on breathing with great vehemence, not from a difficulty of inspiration, but from an eager avidity for more air. When the bags were exhausted and taken from me, I continued breathing with the same violence; then suddenly starting from the chair, and vociferating with pleasure, I made towards those that were present, as I wished they should participate in my feelings. I struck gently at Mr. Davy; and a stranger entering the room at the moment, I made towards him, and gave him several blows, but more in the spirit of good humour than of anger. I then ran through different rooms in the house, and at last returned to the laboratory somewhat more composed; my spirits continued much elevated for some hours after the experiment, and I felt no consequent depression either in the evening or the day following, but slept as soundly as usual."

Dr. Roget states as follows:—"The effect of the first inspirations of the nitrous oxide was that of making me vertiginous, and producing a tingling sensation in my hands and feet; as these feelings increased, I seemed to lose the sense of my own weight, and imagined I was sinking into the ground. I then felt a drowsiness gradually steal upon me, and a disinclination to motion: even the actions of inspiring and expiring were not performed without effort; and it also required some attention of mind to keep my nostrils closed with my fingers. I was gradually roused from this torpor by a kind of delirium, which came on so rapidly that the air-bag dropt from my hands. This sensation increased for about a minute after I had ceased to breathe, to a much greater degree than before, and I suddenly lost sight of all the objects around me, they being apparently obscured by clouds, in which were many luminous points, similar to what is often experienced on rising suddenly and stretching out the arms, after sitting long in one position. I felt myself totally incapable of speaking, and for some time lost all consciousness of where I was, or who was near me. My whole frame felt as if violently agitated: I thought I panted violently; my heart seemed to palpitate, and every artery to throb with violence; I felt a singing in my ears; all the vital motions seemed to be irresistibly hurried on, as if their equilibrium had been destroyed, and everything was running headlong into confusion. My ideas succeeded one another with extreme rapidity, thoughts rushed like a torrent through my mind, as if their velocity had been suddenly accelerated by the bursting of a barrier which had before retained them in their natural and equable course. This state of extreme hurry, agitation, and tumult, was but transient. Every unnatural sensation gradually subsided; and in about a quarter of an hour after I had ceased to breathe the gas, I was nearly in the same state in which I had been at the commencement of the experiment. I cannot remember that I experienced the least pleasure from any of these sensations. I can, however, easily conceive, that by frequent repetition I might reconcile myself to them,

and possibly even receive pleasure from the same sensations which were then unpleasant. I am sensible that the account I have been able to give of my feelings is very imperfect. For, however calculated their violence and novelty were to leave a lasting impression on the memory, these circumstances were for that very reason unfavourable to accuracy of comparison with sensations already familiar. The nature of the sensations themselves, which bore greater resemblance to a half-delirious dream than to any distinct state of mind capable of being accurately remembered, contributes very much to increase the difficulty, and as it is above two months since I made the experiment, many of the minuter circumstances have probably escaped me."

Nitrous oxide is not permanently elastic; for by subjecting it to a pressure of about 50 atmospheres at the temperature of 45° , Mr. Faraday obtained it in the liquid form. It was thus procured by sealing up some nitrate of ammonia in a bent tube and heating it, while the other end was kept cool. Many explosions occurred with very strong tubes, and the experiment is always attended with risk. The tube, when cooled, is found to contain two fluids: the heavier is water, a little acid; the lighter, *liquid nitrous oxide*; it is limpid, colourless, and so volatile, that the heat of the hand generally makes it disappear in vapour. The application of ice and salt condenses it again. It has not been congealed by cold. Its refractive power is less than that of any known fluid. A tube being opened in the air, the nitrous oxide immediately burst into vapour. Another tube was opened under water, and the vapour collected and examined proved to be nitrous oxide. (*Phil. Trans.*, 1823, p. 195.)

Nitrous oxide supports combustion, and a taper introduced into it has its flame much augmented, and surrounded by a purplish halo. Phosphorus and sulphur, when introduced in a state of vivid ignition into this gas, are capable of decomposing it, and burn with the same appearance nearly as in oxygen; but if, when put into the gas, they are merely burning dimly, they then do not decompose it, and are extinguished; so that they may be melted in the gas, or even touched with a red-hot wire without inflaming. Charcoal, and many of the metals, also decompose nitrous oxide at high temperatures.

At a red heat this gas is decomposed, and two volumes of it are resolved into two volumes of nitrogen and one volume of oxygen, so that it thus suffers an increase of bulk. For experiments of this kind the following simple apparatus may be used; it consists of two bladders, one of which is filled with the gas, and the other empty, attached to the

extremities of a coated porcelain or platinum tube, which traverses the body of a furnace. The bladders are supplied with stop-cocks,

and the gas is squeezed from one to the other when the tube is red-hot.

The analysis of this gas may also be effected by detonation with hydrogen. When a mixture of one volume of nitrous oxide and one volume of hydrogen is fired by the electric spark, water is produced, and one volume of nitrogen remains. Now, as one volume of hydrogen takes

half a volume of oxygen to form water, nitrous oxide must consist of two volumes of nitrogen and one volume of oxygen; these three volumes being so condensed, in consequence of chemical union, as only to fill the space of two volumes. The specific gravity of nitrogen, compared with oxygen, is very nearly as 14 to 16; the composition, therefore, of the nitrous oxide, may be represented as annexed: and as

Nitrogen.	Oxygen.		Nitrous Oxide.
14	8	=	22

	Grains.
100 Cubic inches of nitrogen weigh	30·166
50 " oxygen 	17·054
100 " nitrous oxide 	47·220

Hence, regarding this gas as a *protoxide*, the equivalent number of nitrogen will be 14, or, according to Dr. Turner and Berzelius, 14·15 (*Phil. Trans.*, 1833), and nitrous oxide will be constituted as follows:—

				Davy.	Volumes.	S. G.	100 C.I.
Nitrogen	1	.. 14	.. 63·6	.. 63·3	.. 1·0	.. 0·97	.. 30·166
Oxygen	1	.. 8	.. 36·4	.. 36·7	.. 0·5	.. 0·55	.. 17·054
Nitrous oxide	1	22	100·0	100·0	1·0	1·52	47·220

DEUTOXIDE OF NITROGEN, BINOXIDE OF NITROGEN, NITRIC OXIDE, or NITROUS GAS, ($n + ^2O$) or \ddot{N} or NO^2 , was first procured by Mayow (*History of Chemistry*, p. 36), but its properties were first accurately studied by Priestley. It is usually obtained by presenting certain substances to *nitric acid*, which abstract a portion of its oxygen, leaving the remaining elements in such proportions as to constitute the gas in question; for this purpose some copper-filings or clippings may be put into a gas-bottle with nitric acid diluted with thrice its bulk of water; an action ensues, red fumes are produced, and there is a copious evolution of the gas, which may be collected and preserved over water. The first portions should be rejected, as containing nitrogen and nitrous acid gas. Nitric oxide is presently recognised by the red fumes which it produces when brought into the contact of air.

Nitric oxide is a colourless, uncondensable gas; its specific gravity to hydrogen is as 15 to 1. 100 cubic inches weigh 32·137 grains; and, compared with air, its specific gravity is as 1·038 to 1000. According to Thomson its specific gravity is 1·0416, and at the temperature of 32° 100 cubic inches weigh 34·1543 grains. Under common circumstances it is permanent over water; but if agitated with water previously deprived of air by long boiling, it is dissolved in the proportion of about 1 volume to 20. This solution, when long kept, is found to contain nitrate of ammonia, resulting from the joint decomposition of the nitric oxide and the water.

It is instantly fatal to animals; but as it will always meet with a sufficiency of oxygen in the lungs, to convert a part of it into nitrous acid, its abstract effects cannot be determined. An account of an attempt to breathe it will be found in Sir H. DAVY'S *Researches*, &c., p. 475. When it has been washed with water it is not acid, as may be proved by

the colour of litmus remaining unchanged by it. It extinguishes the flame of a taper, and that of sulphur, but phosphorus readily burns in it, if introduced in intense ignition, although it also is extinguished unless it be in vivid combustion. In this case the phosphorus decomposes the gas, nitrogen is evolved, and phosphoric acid formed. Charcoal also decomposes it at a high temperature, the results being carbonic acid and nitrogen.

Nitric oxide is not altered by a low red-heat, but it is decomposed when passed and repassed through small tubes heated to bright redness, more especially if the heated surface is increased by filling them with fragments of rock crystal: it does not detonate when mixed with two volumes of hydrogen, and subjected to the electric spark; a succession of sparks, however, passed through such a mixture, slowly effects the decomposition of a portion of the gas: the same mixture is also decomposed by spongy platinum at common temperatures, and water and ammonia are formed. When this mixture with hydrogen is kindled by a taper it burns with a green flame, and water and nitrogen are the products. Dr. Henry has shown that nitric oxide detonates with ammonia (*Phil. Trans.*, 1809,) in the proportion of 150 measures of the former to 100 of the latter. These gases also slowly act upon each other at common temperatures. Gay Lussac found that in about a month they were reduced to half their joint volume, and that nitrogen was evolved. Some substances which have a strong attraction for oxygen, effect a partial decomposition of the nitric oxide, and convert it, at common temperatures, into nitrous oxide; such, for instance, as moist iron-filings, some of the alkaline sulphurets, some of the sulphites, and protochloride of tin; in which cases two volumes of nitric oxide afford one of nitrous oxide. Nitric oxide may also be decomposed by the action of some of the metals at high temperatures, which absorb its oxygen. Sir H. Davy decomposed it by heated arsenic, and by the ignition of charcoal. (*Elements*, 260.) Gay Lussac

Nitrogen.	Oxygen.	Nitric Oxide.
14	8	
	8	30

decomposed 100 measures of it by the action of heated potassium: 50 measures of pure nitrogen remained, and the loss of weight corre-

sponded to 50 measures of oxygen; so that one volume of nitric oxide is thus resolved into equal volumes of oxygen and nitrogen. (*Mémoires d'Arcueil*.) Nitric oxide, therefore, is constituted of one volume of nitrogen and one volume of oxygen, combined as in the above diagram, without change of volume;

or 50 Cubic inches of nitrogen, weighing . . .	Grains.
and 50 " oxygen " . . .	15·083
form 100 " nitric oxide " . . .	17·054
	32·137

The following, therefore, is the composition of this gas:—

				Berzelius.	Vols.	Sp. Gr.	100 C.I.
Nitrogen . .	1 . .	14 . .	46·67 . .	46·754 . .	1 . .	0·97 . .	15·08
Oxygen . .	2 . .	16 . .	53·33 . .	53·246 . .	1 . .	1·11 . .	17·05
Nitric oxide	1 . .	30 . .	100·00 . .	100·000 . .	2 . .	1·04 . .	32·13

The most characteristic property of nitric oxide, by which it is immediately distinguished from all other gases, is, that of forming the red fumes of nitrous acid vapour when mixed with oxygen: hence these gases are mutually used to detect each other's presence; and as the nitrous acid is wholly absorbed by water, oxygen may be abstracted from any gaseous mixture containing it in an uncombined state, by the addition of a sufficient quantity of nitric oxide; and, on the other hand, nitric oxide may be removed by the addition of oxygen. Priestley, who was the first to attempt accurate experiments upon this subject, conceived that the absorption was at all times uniform; but subsequent experiments have shown that it is subject to variation, more especially dependent upon the presence or absence of water. Although, therefore, nitric oxide may be conveniently used to ascertain the presence of oxygen, it cannot be relied on as an indicator of its proportional quantity; and although Dalton (*Ann. of Phil.*, x. 38,) and Gay Lussac (*Mém. d'Arcueil*, ii. 247,) have each proposed methods by which they conceive accuracy may be ensured, they are not such as to admit of general application. The best mode of using the nitric oxide to determine the proportion of oxygen to that of nitrogen in the atmosphere, will be noticed under the head of Atmospheric Air (EUDIOMETERS).

Solutions of the protochloride and protosulphate of iron have the property of absorbing nitric oxide gas; the colour of these solutions is deep olive, and they speedily absorb oxygen when exposed to, or agitated with air, or other mixtures containing it. (See EUDIOMETERS.) This property also enables us to ascertain the purity of nitric oxide, which ought to be wholly absorbed by the solution of iron: some nitrogen or nitrous oxide are thus generally detected in it, and remain unabsorbed. According to Peligot (*Ann. C. and P.*, liv. 17), the proportion of nitric oxide absorbed by protosulphate of iron is definite, and in the ratio of one equivalent of the nitric oxide to four of the protoxide of iron; by exposure to a vacuum the nitric oxide escapes and the salt of iron remains unaltered; but when heated, a part only of the nitric oxide is evolved, and part is decomposed, and peroxide of iron and ammonia are formed: when this solution is exposed to air or oxygen, nitric acid is ultimately produced.

When nitric oxide is perfectly dry, chlorine exerts no action upon it, but the presence of water causes an immediate change; it is decomposed, and, furnishing oxygen to the nitric oxide, and hydrogen to the chlorine, nitrous and hydrochloric acids are generated. It was the presence of water which misled those who thought that the red fumes produced by mixing nitric oxide and chlorine, not carefully dried, resulted from the existence of oxygen in chlorine.

CHLORONITROUS GAS.—According to E. Davy (*Phil. Mag.*, ix. 355,) when fused chloride of sodium is moistened with nitric acid, a pale reddish yellow gas is evolved, composed of equal volumes of chlorine and nitric oxide, combined without condensation.

HYPONITROUS ACID. AZOTOUS ACID. NITROUS ACID of Graham, Berzelius, and most foreign authors. ($n + 30$) or \underline{n} , or NO_3 or $\ddot{\text{N}}$.—Gay Lussac concluded, from his experiments, that there exists a compound of nitrogen and oxygen intermediate between nitric oxide and nitrous acid,

which he termed *pernitrous acid*, but to which the term *hyponitrous acid* is more applicable. (*Ann. de Chim. et Phys.*, i. 399.) He found by mixing nitric oxide and oxygen in tubes standing over mercury, and containing a little concentrated solution of potassa, that 400 volumes of nitric oxide were condensed under such circumstances by 100 of oxygen. When, however, he attempted to decompose the *hyponitrite of potassa* thus obtained, nitric oxide was evolved, and nitrous acid formed. The liquid hyponitrous acid, he says, may be obtained by the distillation of nitrate of lead; it passes over in the form of a red vapour, condensable in a receiver surrounded by ice; it evolves nitric oxide when diluted with water: it boils at 80° . There is, however, reason to believe that the compound thus obtained is chiefly nitrous acid; but considerable difficulty occurs in reconciling the opinions of Gay Lussac and Berzelius upon these acids, the latter chemist applying the term *nitrous acid* (*Salpetrichte Säure*) to the pernitrous (hyponitrous) acid of the former.

Dulong obtained hyponitrous acid mixed with nitrous acid, by passing a mixture of 1 measure of oxygen with somewhat more than 4 of nitric oxide, first through a tube filled with fragments of porcelain to ensure perfect mixture, and afterwards through a bent tube, cooled below 0° : the acid collected in the curvature was a dark-green fluid, more volatile

Nitrogen.	Oxygen.
14	8
	8

than nitrous acid, and when distilled leaving a yellow fluid, which appeared to be nitrous acid. This acid, as well as the nitrous acid, appears to form a crystallizable compound with the hydrous sulphuric acid, which we shall describe afterwards. The component volumes of nitrogen and oxygen in the hyponitrous acid are, as in the

annexed diagram, 1 and 1.5; or it consists of

						Volumes.		
Nitrogen	..	1	..	14	..	36.8	..	} = Nitric oxide 2.0 Oxygen 0.5
Oxygen	..	3	..	24	..	63.2	..	
<hr/>								
Hyponitrous acid	1	..	38	..	100.0			

The hyponitrous acid appears to form distinct salts by combining with the salifiable bases. When, for instance, nitrate of potassa or nitrate of baryta are heated, oxygen is evolved, and a soluble *hyponitrite* remains. When nitric oxide gas is kept for some weeks in contact with a strong solution of potassa, it is partly converted into nitrous oxide, and the solution yields regular crystals of *hyponitrite of potassa*; 100 volumes of nitric oxide left 25 of nitrous oxide: the acid, therefore, which was absorbed, consisted of 100 volumes of nitrogen, and 150 of oxygen. According to Berzelius, several of the hyponitrites are best obtained by boiling metallic lead in a solution of nitrate of lead, by which a *hyponitrite of lead* is formed: this salt may then be decomposed by sulphates, which form sulphate of lead, and the hyponitrous acid unites to the base of the original sulphate.

When the acid liquid obtained by distilling nitrate of lead, is added to sulphuric acid, it forms a peculiar crystallizable compound. Nitric oxide is not of itself absorbed by sulphuric acid.

NITROUS ACID. HYPONITRIC ACID. PEROXIDE OF NITROGEN (Graham).

($n + 40$) or \bar{n} or NO_4 or $\ddot{\text{N}}$. When two volumes of nitric oxide and one volume of oxygen are mixed in an exhausted glass vessel, the gases combine with the evolution of heat consequent upon their mutual condensation, and form *nitrous acid vapour*, which is condensible into a liquid at 0° . The specific gravity of this liquid is 1.45; at 32° it is pale yellow; but at 60° deep orange: it boils at 82° , and when exposed to the air at common temperature, gradually evaporates in yellow fumes. (DULONG, *Ann. de Chim. et Phys.*, ii.) When a mixture of the gases, in the above proportions, is propelled through a tube cooled to 0° , the liquid acid is at once obtained, and it then appears the same as that obtained by the distillation of dry *nitrate of lead*. If the gases be mixed over water, hyponitrous acid and nitric acid are formed, and it is difficult in any way to obtain their total condensation or absorption by the water in the above proportions.

Nitrous acid vapour supports the combustion of phosphorus, and of charcoal, but extinguishes sulphur. It is readily absorbed by water. Its colour, like the liquid acid, varies with the temperature; becoming darker when heated, and paler when cooled; it has a very peculiar odour, which strongly adheres to the hair and to woollen clothing. Nitrous acid does not apparently unite with the bases, but forms with them *hyponitrites* and *nitrates*, hence it has been regarded as a compound of hyponitrous and nitric acids: when passed over baryta and other bases, at a temperature of between 300° and 400° , it is very rapidly absorbed with the evolution of heat, and the products are, according to Gay Lussac, as just stated. (*Ann. de Chim. et Phys.*, i.)

Nitrous acid vapour is constituted of one volume of nitrogen, and two

NITRIC ACID. AZOTIC ACID. ($n + 50$) or n' or NO_5 or $\ddot{\text{N}}$.—The composition of this acid was first demonstrated by Cavendish, in 1785, (*Phil. Trans.*) He produced it by passing a succession of electric sparks through a mixture of 7 volumes of oxygen and 3 of nitrogen. This experiment has more lately been verified by Faraday (p. 325.) Nitric acid is also formed when nitric oxide is slowly added to an excess of oxygen gas, over water. In this way 4 volumes of nitric oxide condense 3 volumes

of oxygen; but nitric oxide and oxygen never combine in these proportions without the presence of water, or a base.

Nitric acid is usually obtained by the distillation of purified *nitre* with sulphuric acid, of which materials different proportions are employed. The nitric acid of commerce, which is generally red and fuming, in consequence of the presence of nitrous acid, is procured by the distillation of two parts of nitre with one of sulphuric acid; these proportions afford about one part of orange-coloured nitric acid of the specific gravity of 1.48. Upon the large scale, 112 lbs. of nitre, and 56 of sulphuric acid, yield from 50 to 52 lbs. of nitric acid. Some manufacturers employ three parts of nitric and two of sulphuric acid, and the *London Pharmacopœia* directs equal weights, by which a nearly colourless nitric acid is afforded, provided the distillation be conducted at as low a temperature as possible. If the acid is not required in a concentrated state, the sulphuric acid may be previously diluted with its weight of water. Nitrate of soda being cheaper than nitrate of potassa, is also frequently resorted to as a source of nitric acid.

It will appear, by referring to the article *Sulphuric Acid*, that it contains in its liquid state one proportional of dry acid and *one* of water; whereas liquid nitric acid contains one proportional of dry acid and *two* of water: hence the requisite excess of sulphuric acid, where colourless and perfect nitric acid is to be obtained; hence, too, the red colour of the acid of commerce, in consequence of the smaller quantity of sulphuric acid generally used by the manufacturer, the deficiency of water occasioning the nitric acid to be resolved into nitrous acid and oxygen. This will be more apparent by reference to the article *Bi-sulphate of Potassa*. According to Mr. Phillips, the strongest nitric acid of commerce is a sesquihydrate, containing one atom of nitric acid and one and a half of water.

The distillation of nitric acid may be conducted upon the small scale in a tubulated glass retort *a*, with a tubulated receiver *b*, passing into the

bottle *c*. The requisite heat is obtained by the lamp *d*, and the whole apparatus supported by the brass stands with sliding rings *e e*.

But the manufacturer who prepares nitric acid upon a large scale, generally employs distillatory vessels of stone-ware. The following wood-cut represents the arrangement of the distillatory apparatus for the production of common *aqua fortis*: it consists of an iron pot, set in brick-work, over a fire-place; an earthen head is luted upon it, communicating with two or more receivers of the same material, furnished with earthenware stop-cocks, the last of which has a tube of safety dipping into a basin of water.

293

The nitric acid of commerce, as obtained by the above processes, is always impure, and hydrochloric and sulphuric acids may generally be found in it. The former may be detected by *nitrate of silver*, and the latter by a dilute solution of *nitrate of baryta*. For pharmaceutical purposes, the ordinary acid is generally sufficiently pure. If, however, pure nitre and pure sulphuric acid be employed in its production, and the latter not in excess, there is little apprehension of impurity in the resulting acid. If the acid is coloured by the presence of nitrous acid, it is rendered colourless by boiling, which is best performed in a retort, with a loosely-attached receiver: the nitrous acid passes over.

Nitric acid is a colourless liquid, extremely sour and corrosive, and very intense in its action upon the greater number of inflammable bodies, to which it imparts oxygen, and by which it is resolved into some of the inferiorly-oxidized compounds. Its specific gravity, as usually obtained, fluctuates between 1.4 and 1.5. At 247° , when of the specific gravity 1.40, it boils and distils over without change, but the dilute acid is strengthened by boiling; and the strongest acid boils at a lower temperature than that which is of a somewhat less specific gravity. The following table of boiling-points has been given by Mr. Dalton, which shows that

the boiling-point of the acid of the specific gravity 1.42, composed of 1 atom of real acid and 4 atoms of water, is the maximum. This is called by Mr. Graham "the proper *nitrate of water*"; and of the four atoms of water which it contains, one is combined with the acid, as base, and may be named *basic water*, while the other three are in combination with the nitrate of water, and may be termed the *constitutional water* of the salt." He represents this acid in symbols, thus, $\text{HO}, \text{NO}_5 + 3\text{HO}$.

Acid of specific gravity 1.50 boils at 210°

At -40° the concentrated acid congeals. When diluted with half its weight of water it freezes at about -2° . When exposed to the air it exhales fumes, and gradually absorbs water, so that its bulk becomes increased, and its specific gravity diminished. It suffers a partial decomposition when exposed to light, becoming yellow and evolving oxygen, so that it should be kept in a dark place, and especially excluded from the direct rays of the sun. By distilling nitric acid (sp. gr. 1.4) twice successively from four times its weight of sulphuric acid, Gay Lussac increased its density to 1.510. In this state he found it remarkably susceptible of decomposition by heat or light. (*Ann. de Chim. et Phys.*, i.) According to Thenard, a mixture of 1 part of nitric and 4 of sulphuric acid gently heated, affords oxygen and nitrous acid, the sulphuric acid becoming diluted by the abstraction of the water of the nitric acid.

When nitric acid is mixed with snow, the latter is suddenly liquified, and intense cold is produced. Nitric acid, of the sp. gr. 1.5, mixed with half its bulk of water, occasions an elevation of temperature in the mixture $= 112^\circ$: 58 parts of the acid with 42 of water, both at 60° , give, on mixture, a temperature of 140° . (URE, *Quarterly Journal*, iv. 298.) On diluting the red fuming acid it assumes various tints of blueish green dependent upon the quantity of water added.

Nitric acid has not been obtained in a *dry*, or anhydrous state; the liquid acid is a compound of the anhydrous acid and water, or in the language of Mr. Graham, a *nitrate of water*, and some of the salts called *nitrates*, (such as *nitrate of potassa*), are compounds of the anhydrous acid, and a salifiable base. The *anhydrous nitric acid* is constituted of one volume of nitrogen and two volumes and a half of oxygen, as in the annexed diagram.

It is therefore a compound of

The liquid nitric acid in its utmost state of concentration (sp. gr. 1·5), consists, according to Phillips, of one equivalent of anhydrous acid and one and a half of water. According to Dr. Ure, the acid of a specific gravity of 1·486 contains one equivalent of real acid and two of water: hence the following table:—

	Sp. gr.=1·5.			Sp. gr.=1·486.		
Anhydrous acid	1	54	80	1	54	75
Water	1½	13·5	10	2	18	25
	1	67·5	100	1	72	100

The following table, drawn up by Dr. Ure, exhibits the quantity of dry acid and of liquid acid (sp. gr. 1·5) at different densities; (*Quarterly Journal*, iv. 297, and *Dictionary*, p. 71, Sec. Edit;) the quantity of anhydrous acid in the liquid acid of sp. gr. 1·50 being assumed = 79·7. The column of dry acid shows the weight which any salifiable base would gain by uniting with 100 parts of the liquid acid of the corresponding specific gravity.

1	15	28·571	1·2012

Nitric acid may be decomposed by passing its vapour through a red-hot porcelain tube; oxygen is given off, nitrous acid gas is produced, and a quantity of diluted acid passes over into the receiver, having escaped decomposition; so that it is thus proved to consist of nitrous acid, oxygen, and water. At a white heat, oxygen, nitrogen, and water, only, are evolved. When strong nitric acid was electrolysed, no gas appeared at the negative electrode, but nitrous acid, and apparently nitric oxide, were formed there, which rendered the acid red and effervescent. In dilute nitric acid, gas appeared at the negative electrode, its quantity being varied by variations either in the strength of the acid or of the voltaic current: the gas at the anode was always oxygen, that at the cathode, hydrogen. When the quantity of products was examined by the voltameter, the oxygen, whether from strong or weak acid, was always in the same proportion as from water. When the acid was diluted to sp. gr. 1·24 or less, the hydrogen also proved to be in the same quantity as from water; hence Mr. Faraday concludes, that nitric acid does not undergo electro-chemical decomposition, but the water only: that the oxygen at the anode is always a primary result, but that the products at the cathode are often secondary, and due to the reaction of the hydrogen upon the acid. (*Phil. Trans.*, 1834, 96.)

According to Mr. Daniell the result of the electrolysis of nitric acid, composed of one atom of anhydrous acid and one of water, is attended by the evolution of hydrogen at the cathode, and of a compound (which he calls *oxynitron*) of 1 atom of nitrogen and 6 of oxygen, at the anode; hence $(n + 5o) + (h + o)$ becomes in such case $(n + 6o) + h$. (*Phil. Trans.*, 1840, p. 223.)

When nitric oxide is passed through concentrated nitric acid, it is decomposed, and nitrous acid is formed, partly by the acquisition of oxygen by the oxide, and partly by its loss by the acid. Dr. Turner observes, that "The nitrous acid thus derived from two sources gives a colour to the nitric acid, the depth and kind of which depend upon the quantity of the deutoxide of nitrogen which has been employed. The

first portion communicates a pale straw-colour, which gradually deepens as the absorption of the deutoxide continues, till the nitric acid has acquired a deep orange hue, together with all the characters of strong, fuming nitrous acid. But the solution still continues to absorb the deutoxide, and, in doing so, its colour passes through different shades of olive and green, till it becomes greenish-blue. By applying heat to the blue liquid, the deutoxide of nitrogen is evolved, and in proportion as it escapes, the colour of the solution changes to green, olive, orange, and yellow; at length becoming pale as at first. Nitrous acid vapours are likewise disengaged as well as the deutoxide. These phenomena are very favourable to the view that the conversion of the orange-colour into olive, green, and blue, is owing to the formation of hyponitrous acid." (*Elements of Chem.*, 5th ed., 290.)

Some of the metals, such as copper, tin, and silver, are at first without action on concentrated nitric acid, but become vehemently active upon the addition of a little water. It often happens, in such cases, that the metal combines with the oxygen of the water, and that the evolved hydrogen unites to the nitrogen of the acid, forming ammonia, which combines with the undecomposed acid. Poured upon hot iron-filings or melted bismuth, zinc, or tin, nitric acid causes a combustion of the metals.

The facility with which nitric acid imparts oxygen, renders it a valuable oxidizing agent in many chemical operations: phosphorus and most of the metals decompose it at common temperatures, and sulphur and carbon, when aided by heat. It acts energetically often, when diluted, upon the greater number of animal and vegetable substances, and mutual decompositions ensue. A drachm of oil of turpentine mixed with half a drachm of sulphuric acid, instantly bursts into flame upon the addition of a drachm of nitric acid. A piece of glowing charcoal thrown upon the surface of the concentrated acid, burns vehemently with the evolution of red fumes (BERZELIUS). Oxalic, malic, and carbonic acids, are the common products of the action of dilute nitric acid upon most vegetable and animal substances: fatty matter, ammonia, and hydrocyanic acid are also sometimes formed. It tinges the greater number of animal substances of a yellow colour, and permanently stains the nails and cuticle; it is hence employed in the production of yellow patterns upon coloured woollen goods. It is used in fumigations to destroy contagious and infectious matter, more especially in inhabited apartments, where chlorine would prove injurious; for this purpose nitrate of potassa and sulphuric acid are mixed in a saucer, and the evolution of the nitric acid vapour aided by a gentle heat; but it is not so effective as chlorine. In pharmacy, and a variety of other processes, it is susceptible of interesting applications: it is used for etching on copper, and as a solvent for tin in the preparation of valuable mordants used by dyers and calico printers: it is an important agent in metallurgy, and especially in the art of assaying. In medicine it is prescribed as a tonic; and occasionally in syphilitic, hepatic, and eruptive disorders; and in surgery as an energetic caustic. In the bite of rabid animals, if immediately applied to the wound, there is every reason to believe that it would destroy the poison and prevent its consequences.

The salts which nitric acid forms, and which are termed *nitrates*, are all soluble in water; and hence neither its presence nor quantity can be determined by any precipitating re-agent. When uncombined, it is easily recognised by the facility with which it attacks copper, causing the evolution of nitric oxide, and affording a blue solution; and by the formation of *nitre*, when it is saturated with potassa, which salt readily crystallizes in long six-sided prisms. When hydrochloric acid is added to a solution of a *nitrate*, chlorine is evolved, and the liquid acquires the power of dissolving gold-leaf; but as the action of hydrochloric acid on the salts of chloric and bromic acid also furnishes a solution which dissolves gold, no inference can be drawn from the experiment, except the absence of those acids has been previously ascertained.

The following method of detecting the presence of nitric acid has been suggested by Dr. Liebig, who says that it is effective when not more than a four-hundredth part of the acid is present. The liquid to be examined must be mixed with a sufficiency of sulphuric solution of indigo, to acquire a distinct blue colour; a few drops of concentrated sulphuric acid are then added, and the whole boiled; if the liquid contain a nitrate, it will either be bleached or rendered yellow. By adding a little common salt to the liquid before applying heat, a five-hundredth part of nitric acid may easily be discovered. (*Ann. de Chim. et Phys.*, xxxv. 80.)

M. Runge proposes to detect nitric acid and its combinations as follows:—"Pour a solution of proto-chloride of iron upon the surface of an amalgam of zinc, and then place a crystal of nitre on the latter in the fluid: a dark band immediately forms around the crystal, sometimes extending over the whole surface of the amalgam. All the nitrates, as well as nitric acid, act in this manner; but other salts, such, for instance, as the chlorates, produce no such effect, so that a very sensible test of the presence of nitric acid is thus afforded. It is necessary that the solution employed be a proto-salt of iron. If nitric acid is supposed to exist in a liquid, it should be saturated with potassa, evaporated to dryness, and the dry mass tried. Salts of copper and silver must not be present." (*Annalen der Physik*, 1827.)

Another test for nitric acid has been proposed by Richemont: the liquid suspected to contain a nitrate is mixed with an equal bulk of sulphuric acid, and when cool a few drops of a strong solution of protosulphate of iron are added; nitric oxide is evolved, which produces a purplish tint, even when the quantity of nitric acid is very small. Dr. Turner observes that another character which may be useful consists in mixing the supposed nitric acid or nitrate with dilute sulphuric acid, in a tube, adding a few fragments of zinc, and setting fire to the hydrogen as it issues; if nitric acid be present the flame of the hydrogen will have a greenish-white tint, due to the admixture with binoxide of nitrogen. "A very delicate test," he adds, "has been proposed by O'Shaugnessy, founded on the orange red, followed by a yellow colour, which nitric acid communicates to morphia. The supposed nitrate is heated in a test tube with a drop of sulphuric acid, and then a crystal of morphia is added. It is advisable to try the process in a separate tube with the sulphuric acid alone, in order to prove the absence of nitric acid in it."

Nitric acid is an important agent in the operations of analysis. It is

used,—1. to oxidize and dissolve the metals, and to separate them from the few which are not acted upon by it, especially gold and platinum: it is of constant use in the process of assaying, for separating silver from gold. 2. To separate certain metals in the form of insoluble peroxides, such as antimony and tin, from those which yield soluble oxides, as in the separation of tin from mercury; it also is useful in the peroxidization of iron and manganese, by which those metals are rendered insoluble in nitric acid, and thus separable from soluble earths, &c. 3. Dilute nitric acid separates sulphur from the metals in the form of an insoluble magma, or gray powder, as in the analysis of sulphuret of copper, of lead, or of silver; if concentrated, it acidifies sulphur and arsenic. 4. The concentrated acid detects sulphuretted hydrogen by the production of a white cloud, and the destruction of its fetid odour. 5. It is used as a solvent to determine the nature of certain precipitates, and to separate the soluble from the insoluble. The precipitates formed by the vegetable acids, by succinic acid, by phosphoric acid, and by arsenic acid in the solutions of baryta, of lime, and of lead, are easily soluble in dilute nitric acid; but the precipitate by sulphuric acid in solutions of baryta is perfectly insoluble, and that in solution of lead difficultly soluble, requiring about 100 parts of the acid. 6. Nitric acid is a test of certain organic substances: it generally tinges those containing nitrogen of a yellow colour; it detects strychnia, by rendering it red; the nitric solution of uric acid leaves a red residue on evaporation; it changes polychroite to green, and guaiacum to blue and green. It distinguishes gum from starch, by converting the former into mucous or sacclactic acid: cork it converts into suberic acid. 7. Many of the nitrates, and the nitro-hydrochloric acid, are used as tests. (PFAFF, *Handbuch der Analytischen Chemie*, i. 98, 2nd ed.)

NITRO-HYDROCHLORIC ACID. NITRO-MURIATIC ACID.—This term has been applied to the *Aqua Regia* of the alchemists. When nitric and hydrochloric acids are mixed, they become yellow, and acquire the power of dissolving gold, which neither of the acids possessed separately. This mixture evolves chlorine, a partial decomposition of both acids having taken place, and water, chlorine, and nitrous acid are thus produced; that is, the hydrogen of the hydrochloric acid abstracts oxygen from the nitric to form water: the result must be chlorine and nitrous acid. (DAVY, *Journal of Science and the Arts*, vol. i., p. 67.) The annexed diagram may, perhaps, serve to render these mutual changes more evident. Two parts of hydrochloric and one of nitric acid furnish the most effective mixture; but a solution having the same general properties is obtained by adding nitre to hydrochloric acid, or common salt to nitric acid. According to Berzelius, the mutual decomposition of the two acids proceeds only so far in the first instance as to saturate the liquid with chlorine; but when heat is applied, chlorine is evolved till one of the acids is entirely decomposed. When a metal is put into nitro-hydrochloric acid, it absorbs the chlorine,

and is dissolved; for the liquid cannot become then saturated with chlorine, because the metal combines with it as fast as it is evolved: the application of heat greatly accelerates this action, but much chlorine may be lost by employing too high a temperature. As nitric oxide is evolved during the solution of a metal in nitro-hydrochloric acid, it might be supposed that the hydrogen of the hydrochloric acid had reduced the nitric acid to the state of nitric oxide; but Davy has shown that a mixture of hydrochloric and *nitrous* acids possesses none of the properties of Aqua Regia: consequently, the evolution of nitric oxide depends upon the spontaneous resolution of the produced nitrous acid into nitric acid and nitric oxide. Nitro-hydrochloric acid is the common solvent of gold and platinum, and may, with proper precautions, be used in the separation of those metals from silver, which remains as an insoluble chloride. It furnishes a useful solution of tin; and is employed in the analysis of minerals containing sulphur, to separate and acidify that elementary body.

NITROGEN AND CHLORINE. CHLORIDE OF NITROGEN. TERCHLORIDE OF NITROGEN. ($n + 3C$) or $N Cl_3$.—These gases do not unite *directly*, but the compound may be obtained by exposing a solution of *nitrate* or *hydrochlorate of ammonia* to the action of chlorine, at a temperature of 60° or 70° . The gas is absorbed, and an oil-like fluid, heavier than water, is produced by the union of the nascent nitrogen (evolved in the decomposition of the ammonia of the salt) with the chlorine. It was discovered by M. Dulong, in 1812, (*Ann. de Chim.*, LXXXV.,) and its properties afterwards investigated by Davy. (*Phil. Trans.*, 1813.)

The simplest mode of obtaining this compound, consists in filling a perfectly clean glass basin with a solution of about one part of sal-ammoniac in twelve of water, and inverting into it a tall jar of chlorine. The saline solution is gradually absorbed, and rises into the jar, a film forms upon its surface, and it acquires a deep yellow colour: at length small globules, looking like yellow oil, collect upon its surface, and

240

successively fall into the basin beneath, whence they are most conveniently removed by drawing them into a small and perfectly clean glass syringe, made of a glass tube drawn to a pointed orifice (fig. 240), and having a copper-wire with a piece of clean tow wrapped round it for a piston; in this way a globule may be drawn into the tube, and transferred to any other vessel. Balard obtained this compound by suspending a piece of sulphate of ammonia in a strong solution of hypochlorous acid.

The specific gravity of chloride of nitrogen is 1.6; it is not congealed by cold. Its odour is irritating and peculiar; it very soon evaporates when exposed to air. It is dangerously explosive, and is decomposed with violent detonation by many combustibles, especially phosphorus and fixed oils. In making these experiments, which should be conducted with extreme caution, and the face protected by a mask (Dulong lost an eye and the use of a finger, and Sir H. Davy was wounded in the face

by the effects of its detonation), a small globule of the compound, about the size of a mustard seed, may be cautiously transferred to a clean porcelain basin, half filled with water, and placed under a wire-cage: a very small piece of phosphorus, fixed to the end of a long stick, or a long rod with the extremity dipped in oil, may be then brought into contact with the globule, which instantly explodes with a flash of light, dispersing the water, and breaking the basin to atoms. At 160° it distils without change, but at 212° it explodes, and is decomposed. It was submitted to the action of 125 different substances, by Messrs. Porret, Wilson, and Kirk, of which the following caused it to explode.

* Phosphorus	Linseed-oil	Oil of orange-peel
Phosphuret of lime	Olive-oil	Naphtha
Caoutchouc	Camphorated oil	Strong liquid ammonia
Myrrh	Sulphuretted oil	Fused potassa
Palm-oil	Oil of turpentine	Phosphuretted hydrogen
Ambergris	Oil of tar	Nitric oxide
Whale-oil	Oil of amber	Metallic soaps.

The metals, resins, and sugar, did not cause it to explode. (NICHOLSON'S *Journal*, vol. xxxiv.) Alcohol quietly changes it into a white substance. Mercury and most of the other metals absorb the chlorine, and evolve nitrogen. It gradually disappears when kept in a stopped phial with water, and nitrous and hydrochloric acid are formed by the mutual decomposition of the liquids. In concentrated hydrochloric acid it forms ammonia, and chlorine is evolved. It is also slowly decomposed by dilute liquid ammonia; hydrochlorate of ammonia is formed, and nitrogen evolved.

The existence of nitrogen in nearly all the powerfully-detonating bodies is a singular fact, and the decomposition of this compound is attended by a circumstance observed in some other cases, namely, the appearance of flame or fire, which is here, not the result of condensation and union, but is accompanied by expansion and decomposition; by the separation of two bodies previously combined: the decomposition of the oxides of chlorine already referred to, and that of iodide of nitrogen and of peroxide of hydrogen (oxygenated water) exhibits the same peculiarity.

Chloride of nitrogen appears to yield, by decomposition, 1 volume of nitrogen and 3 of chlorine (and not 4, as originally inferred by Davy); and as the specific gravity of nitrogen to chlorine is as 14 to 36, so it may be said to consist of 1 volume of nitrogen + 3 volumes of chlorine, and, in the state of vapour, it is probable that the four volumes of æriform matter which it affords by decomposition, are condensed into one. It is, therefore, regarded as a compound of

Nitrogen.	Chlorine.	
14	36	
	36	=
	36	36

Nitrogen	1	14	11.5
Chlorine	3	108	88.5
<hr/>			
Chloride of Nitrogen	1	122	100.0

From the experiments of Millon it seems probable that this compound may contain hydrogen. (*Ann. de Ch. et Ph.*, Lxix. 75.)

NITROGEN AND IODINE. IODIDE OF NITROGEN. TERIODIDE OF NITROGEN. ($n + 3i$) or NI_3 .—This compound may be procured by pouring a solution of ammonia upon a very small quantity of iodine. The iodine decomposes part of the ammonia, and, combining with its hydrogen, forms hydriodic acid, and this, uniting with the ammonia, forms hydriodate of ammonia: the nascent nitrogen unites with another portion of iodine, and forms an insoluble black powder, which may be collected by pouring off the liquid, and placing it, while moist, in small parcels upon bibulous paper, where it must be suffered to dry spontaneously. This curious compound was discovered by Courtois. Serullas obtains it by agitating alcoholic solution of iodine with excess of ammonia; it subsides on dilution with water, and must be carefully dried: in this state it does not detonate whilst moist, but if it is put into pure ammonia it explodes when slightly pressed in the liquid. (*Ann. de Chim. et Phys.*, xlii. 201.) Mitscherlich (POGGENDORFF'S *Annalen.*, xiv. 539) has described another method of obtaining this compound. A chloride of iodine is formed by dissolving iodine in nitro-hydrochloric acid; this solution, saturated with ammonia, yields hydrochlorate of ammonia and iodide of nitrogen: the latter may be collected upon a filter, and separated, whilst moist, into small portions; but it is not safe to operate upon more than a few grains of iodine. In this experiment no gas is evolved; one proportional of ammonia reacts upon three proportionals of chloride of iodine, so that a volume of nitrogen combines with three volumes of iodine vapour to produce the detonating compound, and three volumes of hydrogen combine with three of chlorine to form hydrochloric acid.

Iodide of nitrogen, when dry, detonates upon the slightest touch, and the detonation of one portion generally causes the neighbouring ones to explode also. When it detonates, the purple fumes of iodine are perceptible. When left exposed to air it slowly evaporates; and if moist, is gradually resolved into nitrogen or ammonia, and iodic and hydriodic acids. It is decomposed by hot water and by alkaline solutions. Marchand has attempted to show that this compound contains hydrogen (*Ann. de Ch. et Ph.*, Lxxiii. 222), but from Gay Lussac and Colin's researches (*Ann. de Ch.*, xci. 30), it appears to consist of

Nitrogen . . .	1 . .	14 . .	3.6

<hr/>		<hr/>	<hr/>
Iodide of nitrogen	1	389	100.0

BROMIDE OF NITROGEN ($n + 3b$), or NBr_3 , is obtained, according to M. Millon, (*Ann. de Ch. et Ph.*, Lxix. 75,) by gradually adding a solution of an alkaline bromide to the chloride of nitrogen under a thin stratum of water: with bromide of potassium, for instance, bromide of nitrogen and chloride of potassium are the results. Bromide of nitrogen is of dark red colour, and more readily decomposed than the chloride; it has an oily aspect, is heavy, very volatile, and its vapour fetid and very irritating to the eyes. Phosphorus and arsenic cause it to detonate with great

violence: its general characters are analogous to those of the chloride. According to Millon it contains hydrogen, but its composition is probably the counterpart of the chlorides of nitrogen and iodine.

NITROGEN AND HYDROGEN. AMMONIA. VOLATILE ALKALI. TERHYDRURET OF NITROGEN. ($n + 3h$) or A, or NH_3 . — When nitrogen and hydrogen gases are mixed, they show no tendency to combine; they unite, however, under certain peculiar circumstances of evolution, and the result is *ammonia*. This gaseous compound may be obtained by heating a mixture of *quicklime* and *hydrochlorate of ammonia*. Two parts of dry quicklime and one of hydrochlorate of ammonia may be introduced into a small glass retort, and, upon the application of a gentle heat, the gas is evolved. It must be collected over mercury. Towards the latter part of the operation water passes over, which may be arrested in the neck of the retort by the previous introduction of a piece of blotting-paper; or it may be prevented passing over by filling up the bulb of the retort with powdered lime. The theory of the decomposition which here ensues is somewhat complicated, and will be better understood when the nature of lime is explained. Hydrochlorate of ammonia is a compound of hydrochloric acid and ammonia; by the action of the lime (which is an oxide of calcium) the ammonia is expelled in its pure and gaseous form: the hydrochloric acid and the lime then mutually decompose each other, and water and chloride of calcium are the results. The annexed diagram may, perhaps, more clearly explain this.

Ammonia is permanently elastic at common temperatures; by exposing it to intense cold, Guyton supposed that he had observed it to assume a liquid form. (*Ann. de Chim.*, xxix. 290.) But this could not be the case, as it requires for its liquification a pressure of 6·5 atmospheres at the temperature of 50°. (*FARADAY, Phil. Trans.*, 1823, p. 196.) It was most readily obtained in this state by disengaging it in a sealed tube from chloride of silver, which had been previously made to absorb it. It was colourless, transparent, of a specific gravity of 0·76, and its refractive power surpassed that of water.

Ammonia is very pungent and acrid, and of course unrespirable, but when diluted by mixture with common air, agreeably stimulant. It converts most vegetable blues to green, and the yellows to red, properties which belong to the bodies called *alkalis*. Ammonia, therefore, has been termed *volatile alkali*; and the change of colour thus effected by it, is distinguished from that produced by the *fixed* alkalis, by the return of the original tint, when the ammonia flies off by exposure. It saturates the acids, and produces an important class of *ammoniacal salts*, which are recognised by the evolution of ammonia when they are triturated with potassa, soda, or lime.

The specific gravity of ammonia compared with hydrogen is as 8·5 to

1; compared with air it is as 0.590 to 1; 100 cubical inches weigh 18.28 grains; or, at the temperature of 32° , 19.301 grains. (THOMSON.) It extinguishes flame, but forms a difficultly inflammable mixture with common air, and may be burned when issuing from a capillary orifice in an atmosphere of oxygen. When mixed with its volume of oxygen it burns with a feeble explosion. Ammonia is abundantly absorbed by chloride of calcium, as well as by several other chlorides, with which, and with the other haloids, it forms a curious and interesting series of compounds which will afterwards be noticed. If it be required artificially to dry the gas, potassa or lime should be used. (*Quarterly Journal*, v. 74.)

Water, at the temperature of 50° , takes up 670 times its volume of ammonia (780, THOMSON); its bulk is increased, and its specific gravity diminished; that of a saturated solution is 0.875, water being 1.000. The following table shows the quantity of ammonia in solutions of different specific gravities. (DAVY'S *Chem. Phil.*, p. 268.)

100 parts of Sp. Gr.		Of Ammonia.	100 parts of Sp. Gr.		Of Ammonia.
8750	contain	32.50	9435	contain	14.53

According to Dalton, (*New System of Chem.*, ii. 422,) the following are the strengths of solutions of ammonia of different specific gravities, as also their respective boiling-points:—

Specific Gravity.	Grains of Ammonia in 100 grains of the liquid.	Boiling Points.	Volumes of gas in one volume of liquid.
.850	35.3	26°	494
.860	32.6	38	456
.870	29.9	50	419
.880	27.3	62	382
.890	24.7	74	346
.900	22.2	86	311
.910	19.8	98	277
.920	17.4	110	244
.930	15.1	122	211
.940	12.8	134	180
.950	10.5	146	147
.960	8.3	158	116
.970	6.2	173	87
.980	4.1	187	
.990	2.0	196	28

The usual state in which ammonia is employed is in aqueous solution, both in chemistry and medicine. This solution bears the name of *Liquor Ammonia* in the *London Pharmacopæia*. It may be obtained by passing the gas into water in a proper apparatus, or by distilling over the water and gas together. Dr. Turner recommends for this process, the use of equal parts of sal-ammoniac and well-burned quick-lime: the lime is slaked by

the addition of water, and as soon as it has fallen into powder, placed in an earthen pan, and covered, till quite cold, then mixed with the powdered sal-ammoniac and put into a proper retort and heated as long as it gives out gas, which should be conducted by means of a safety-tube of Welter into a quantity of distilled water, equal to the weight of the salt employed. The specific gravity of the solution of ammonia so obtained is .936. (*Elem. of Chem.* 5th ed., 384.)

The following process, recommended by Mr. R. Phillips, answers well. On 9 ounces of well-burned lime pour half a pint of water, and when it has remained in a well-closed vessel for about an hour, add 12 ounces of hydrochlorate of ammonia in powder and three pints and a half of boiling water; when the mixture has cooled, pour off the clear portion, and distil from a retort 20 fluid ounces. The specific gravity of this solution, which is sufficiently strong for most purposes, is 0.954. (*Remarks on London Pharmacopœia*, p. 34.) The specific gravity of the official solution directed in the *Pharmacopœia*, is 0.960.

Liquid ammonia, as this aqueous solution of it is commonly called, should be preserved in well-stopped glass bottles, since it loses ammonia and absorbs carbonic acid, when exposed to air. When heated, ammonia is rapidly given off by it; when concentrated, it requires to be cooled to -40° before it congeals, and then it is apparently inodorous, and of a gelatinous appearance. If a piece of ice be introduced into a jar of ammonia standing over quicksilver, it melts with great rapidity, and liquid ammonia is produced.

A pure and strong solution of ammonia is a bad conductor of electricity, but it becomes a conductor when sulphate of ammonia is dissolved in it, and then, if submitted to electrolytic action, Faraday found that nitrogen was evolved at the anode, and hydrogen at the cathode, the ratio of the volume of the former to that of the latter varying, but being as 1 to about 3 or 4. This result seemed to indicate that the electric current had decomposed the ammonia, and that the nitrogen had been determined towards the positive electrode. But when the electricity used was measured out by the voltmeter, it was found that the hydrogen obtained was exactly in the proportion which would have been supplied by decomposed water, whilst the nitrogen had no certain or constant relation whatever; and upon further experiment, that the water only was electrolyzed and that the nitrogen at the anode was a secondary result, depending upon the chemical action of the nascent oxygen (determined to that surface by the electric current) upon the ammonia. No experiment has hitherto shown any tendency of nitrogen under the influence of the electric current to pass in either direction along its course. (*Phil. Trans.*, 1834, p. 95.)

Dr. Henry (*Phil. Trans.*, 1809) first observed that a mixture of ammonia and oxygen might be fired by an electric spark, and this property furnishes a means of analyzing the alkaline gas. Electricity also decomposes ammoniacal gas. If a succession of electrical sparks be passed through a small portion of the gas confined in a proper tube over quicksilver, it will increase to about twice its original bulk, and lose its easy solubility in water. If the gas thus expanded be mixed with from one-third to one-half its bulk of oxygen, and an electric spark passed through the mixture, an explosion takes place, attended by considerable

diminution. Note the amount of the diminution, divide it by 3, and multiply the product by 2. The result shows the quantity of hydrogen; for 2 measures of hydrogen are saturated by 1 of oxygen. Thus, suppose 10 measures of ammonia, expanded by electricity to 18, and that, after adding 8 measures of oxygen gas, we find the whole (=26 measures) reduced by firing to 6 measures, the diminution will be 20. Then $20 \div 3 = 6.66$; and $6.66 \times 2 = 13.32$ measures of hydrogen gas from 10 of ammonia; and $18 - 13.32 = 4.68$ for the nitrogen gas contained in the product of electrization. Therefore, 10 measures of ammonia have been destroyed and expanded into 13.32 measures of hydrogen and 4.68 of nitrogen gas. (HENRY'S *Elements*, 7th ed., vol. i. p. 233.)

Nitrogen.	Hydrogen.	=	Ammonia.
14	1		
	Hydrogen.		
	1		17
	Hydrogen.		
	1		

It appears from the above, and from the prior experiments of Berthollet, that 1 volume of ammonia is resolved by decomposition into 2 volumes of a mixture of hydrogen and nitrogen, consisting of 3 volumes of hydrogen and 1 volume of nitrogen; hence the annexed diagrams will represent the composition and volume of ammonia.

Such being the volumes of the gases, it follows that if we add the specific gravity of nitrogen to thrice the specific gravity of hydrogen and divide the product by 2, we ought to obtain the specific gravity of ammonia;

$$\begin{array}{rcl} \text{Specific Gravity of nitrogen} & \dots & = 0.972 \\ \text{,, hydrogen} & \dots & 0.0694 \times 3 = 0.208 \end{array}$$

Or,

$$1.180 \div 2 = 0.590$$

50	Cubic inches of nitrogen weigh	15.08
150	,, hydrogen	3.19
100	,, ammonia	18.27

Ammonia, therefore, is a compound of

				Berthollet.	Vols.	Sp. Gr.	100 Cub. In.		
Nitrogen	1	..	14	..	82.35	82.35	1	0.972	30.16
Hydrogen	3	..	3	..	17.65	17.65	3	0.208	6.40
Ammonia	1		17		100.00	100.00	2	0.590	18.28

When ammonia is detonated with excess of oxygen, a portion of nitric acid seems always to be formed: indeed, according to Bischof, this acid is more or less formed in all cases of its combustion with oxygen. He found the limits of combustibility with oxygen to be, on the one hand, 1 ammonia and 0.6 oxygen; and, on the other, 1 and 3.17 by volume.

Ammonia, like most of the compounds of nitrogen, is not permanent at a red heat, and is consequently decomposed when passed through a red-hot tube. If passed over a coil of iron or copper wire in a red-hot porcelain tube, the metals become brittle, but their weight is not altered

According to Thenard (*Ann. de Chim.*, LXXV. 61), when any of the five following metals are enclosed in the tube, they promote the decomposition of ammonia at a temperature below that which it requires *per se*, in the following order: iron, copper, silver, gold, platinum. In all these cases the gas suffers expansion, and is resolved into hydrogen and nitrogen gases, in the above-stated proportions; it furnishes a singular instance of change of properties in consequence of chemical combination. (*a* is a bladder filled with ammonia, which may be passed through the iron tube *b*, placed in the furnace *c*; the gas is decomposed, and hydrogen and nitrogen may be collected over the water in *d*.)

Ammonia is also decomposed when passed over black oxide of manganese, heated red-hot in a porcelain tube; the results, which are *water* and *nitrous acid*, were first observed by the Rev. J. Milner. (*Phil. Trans.*, vol. LXXIX.) *Nitrate of ammonia* is also often formed. Passed through a porcelain tube containing red-hot charcoal, ammonia forms a portion of hydrocyanic acid.

Ammonia is produced synthetically during the decomposition of many animal substances; it is also formed during the violent action of nitric acid upon phosphorus and some of the metals; and by moistened iron-filings exposed to an atmosphere of nitrogen: in these cases the nascent gases unite so as to form a portion of ammonia. Common rust of iron formed by the exposure of iron to a damp atmosphere, also generally contains traces of ammonia. According to Dr. Hare, ammonia is also synthetically formed by the action of spongy platinum on a mixture of 2 volumes of nitric oxide and 5 of hydrogen. For such experiments he recommends platinated asbestos, formed by dipping asbestos into a solution of chloride of platinum and exposing it to a red-heat. There are some other anomalous cases of the evolution and apparent production of ammonia, which are not easily explained, but which have been enumerated and commented upon by Mr. Faraday, in a paper published in the *Quarterly Journal* (vol. xix. p. 16).

Ammonia combines with the acids, and produces a class of salts which, with very few exceptions, are soluble in water, and which evolve the odour of ammonia when mixed with lime or with pure potassa. These salts are, for the most part, entirely dissipated, and, generally speaking, decomposed by heat. Ammonia mixed with the gaseous acids condenses them into white pulverulent compounds; it combines either with half its volume, or with an equal volume, or with two volumes of the acid. The same combination ensues when the volatile acids are brought near free ammonia; and in this way very minute quantities of ammonia may be discovered, by dipping a glass rod into hydrochloric, nitric, or acetic acid, and bringing it near any liquid or substance supposed to evolve ammonia, which will be immediately recognised by white

fumes. The constitution of ammoniacal salts involves many important theoretical considerations respecting the nature of ammonia, which will presently be adverted to.

AMMONIA AND CHLORINE.—When these gases are mixed, a partial decomposition of the former ensues. On mixing 15 parts of chlorine and 40 of ammonia, 5 parts of nitrogen are liberated, and *hydrochlorate of ammonia* is formed. If the gases be perfectly dry, considerable heat is evolved, and a flame is perceived to traverse the vessel in which the experiment is made. This combustion of ammonia in chlorine is well shown by annexing to the beak of a small tubulated retort, containing a mixture of hydrochlorate of ammonia and lime, a bent tube, not too small, the extremity of which terminates in a bottle containing chlorine; on heating the contents of the retort, ammonia is evolved, and as it issues from the tube into the chlorine, it inflames, and continues to burn with a pale lilac flame, producing hydrochlorate of ammonia, and evolving nitrogen. Dr. Thomson employed *chloride of lime* to decompose ammonia, by mixing it with hydrochlorate of ammonia, and collecting the evolved nitrogen. When solutions of chlorine and ammonia are mixed, an effervescence ensues, nitrogen gas is evolved, and hydrochlorate of ammonia formed; and when gaseous chlorine is transmitted in successive bubbles into a strong solution of ammonia, each produces a slight explosion attended by a flash of light. (See p. 405.)

The best mode of showing the mutual action of ammonia and chlorine in solution, is to pour into a tube, about two feet long and half an inch in diameter, sealed at one end, a strong aqueous solution of chlorine, to within about two inches of the top; then gradually to pour upon it liquid ammonia, so as to fill the tube, which is to be closed by the thumb, and inverted into water; the solution of ammonia then rises through that of chlorine, and is decomposed with effervescence, nitrogen being evolved, and hydrochlorate of ammonia retained in solution.

AMMONIA AND CHLORIC ACID. ($A + C'$.) *Chlorate of ammonia* is formed by saturating chloric acid with carbonate of ammonia. It forms very soluble acicular crystals, of a sharp taste, which detonate when thrown upon hot coals. It probably consists of one proportional of each of its components, or 17 ammonia + 76 chloric acid: but its composition has not been experimentally determined. (VAUQUELIN, *Ann de Chim.*, xcv. 97.)

AMMONIA AND HYDROCHLORIC ACID. **HYDROCHLORATE OF AMMONIA.** **MURIATE OF AMMONIA.** **SAL AMMONIAC.** ($n + 3h$) + ($h + c$), or ($A + hc'$), or $NH_3 + HC$ (*Hypothetical CHLORIDE OF AMMONIUM*).—This salt may be produced, directly, by mixing equal volumes of ammonia and hydrochloric acid gases, when an entire condensation ensues. The specific gravity of ammonia compared with hydrochloric acid is as 8.5 to 18.5; therefore, hydrochlorate of ammonia consists of

Ammonia.	Hydrochloric Acid.	Bucholz.			
8.5	18.5	or, { Ammonia . . .	1 . . 17 . .	31.5 . .	31
		{ Hydrochloric acid	1 . . 37 . .	68.5 . .	69
			<hr/> 1	<hr/> 54	<hr/> 106.0
					<hr/> 100

This salt was formerly imported from Egypt, where it was obtained by burning the dung of camels (see PARKES'S *Essays*, ii. 437); it is now abundantly prepared on the continent and in this country, chiefly by the decomposition of *sulphate of ammonia* by chloride of sodium or of magnesium. When obtained by evaporation from its solution in water, it forms octoëdral, cubic, and plumose crystals; but, in commerce, it usually occurs, as procured by sublimation, in colourless and translucent cakes, hard, and somewhat elastic, specific gravity 1.45, and very slightly deliquescent: in this compact state it requires for solution about an equal weight of water at 212°, and three times its weight at 60°, cold being produced during its solution; it also dissolves in alcohol: when heated it sublimes without decomposition in the form of white vapour, and may be even passed through a red-hot porcelain tube without change. It is, however, decomposed when transmitted over ignited iron or copper-wire.

Sal-ammoniac is used in the arts for a variety of purposes, especially in certain metallurgic operations. It is used in tinning, to prevent the oxidation of the surface of copper; and small quantities are consumed by dyers. Dissolved in nitric acid, it forms the *Aqua Regia* of commerce, used for dissolving gold, instead of a mixture of nitric and hydrochloric acids. It is decomposed by the fixed alkalis, and by the alkaline earths.

Native sal-ammoniac occurs massive and crystallized, in the vicinity of volcanoes, and in the cracks and pores of lava near their craters. It has thus been found at Etna, and at Vesuvius, in the Solfaterra near Naples, and in some of the Tuscan lakes. An efflorescence of it is sometimes seen upon pit-coal. Its colour varies, from the admixture of foreign matter, and it is frequently yellow from the presence of sulphur. It is said that considerable quantities of native sal-ammoniac are also found in the country of Bucharia, where it occurs with sulphur in rocks of indurated clay. The ancients, according to Pliny, called this salt *ammoniac*, because it was found near the temple of Jupiter Ammon, in Africa. It has been detected by Dr. Marcet in sea-water. (*Phil. Trans.*, 1822, p. 454.)

AMMONIA AND IODINE.—The mutual action of iodine and ammonia was first studied by Colin. (*Ann. de Chimie*, xci. 262.) Iodine absorbs dry ammoniacal gas, and produces a viscid compound, at first of a metallic appearance, but becoming deep brown and more liquid by excess of ammonia. Added to water this liquid produces a crimson-coloured solution, and yields iodide of nitrogen: it is also soluble in alcohol, and acts more powerfully on organic matter than pure iodine. Exposed to air it ultimately leaves a pale-brown powder, powerfully detonating, and exhibiting a bright light at the moment of explosion. Landgrebe, who has ascertained these facts (POGGENDORFF'S *Annalen*, xiv. 539), considers this as a distinct iodide. It detonates at the temperature of about 80°. The action of iodine on liquid ammonia has been already described. Berzelius regards the iodide of ammonia as an hydriodate of iodide of nitrogen and of ammonia. Bineau states that 100 parts of iodine absorb 20.4 of ammonia, which is in the proportion of 2 atoms of iodine and 3 atoms of ammonia. (*Ann. de Ch. et Ph.*, Lxvii. 228.)

IODATE OF AMMONIA ($i + 5o$) + ($h + 3n$) is obtained by saturating iodic acid with ammonia. It forms small crystals, sparingly soluble in water; it deflagrates, when thrown upon hot coals, with a pale violet flame; heated highly in a tube it explodes, and is decomposed into oxygen, nitrogen, water, and iodine. Its composition has not been experimentally ascertained.

HYDRIODATE OF AMMONIA. ($h + 3n$) + ($h + i$) or ($A + hi$). In a former paragraph the action of iodine on ammonia has been stated to produce a portion of hydriodate of ammonia: this compound may be directly formed by mixing equal volumes of hydriodic and ammoniacal gases; or by saturating liquid hydriodic acid by carbonate of ammonia: it forms very soluble and deliquescent cubic crystals, which are anhydrous, and volatile in close vessels without decomposition. Its aqueous solution dissolves iodine. (GAY LUSSAC, *Ann. de Chim.*, xci.) Hydriodate of ammonia consists of

Ammonia	1	.	17	.	12
Hydriodic acid	1	.	126	.	88
<hr/>					<hr/>		<hr/>		<hr/>
Hydriodate of ammonia					1		143		100

AMMONIA AND BROMINE act on each other with the evolution of nitrogen, and form *hydrobromate of ammonia*; but no *bromide of nitrogen*.

BROMATE OF AMMONIA has not been examined.

HYDROBROMATE OF AMMONIA. ($A + hb$) is a volatile prismatic salt, becoming yellow and slightly acid by exposure to air. It is constituted of equal volumes of gaseous hydrobromic acid and ammonia.

HYDROFLUATE OF AMMONIA. ($A + hf$). According to Berzelius, the neutral hydrofluante is best obtained by heating in a platinum crucible a mixture of one part of hydrochlorate of ammonia with 2.25 parts of fluoride of sodium, both in fine powder: the cover of the crucible should be inverted, and contain water, to be replaced as it evaporates, so as to prevent its temperature exceeding 212° . A gentle heat sublimes the salt, which attaches itself in small prismatic crystals to the cool cover. If the salts were moist, ammonia is evolved, and an acid salt obtained. *Hydrofluante of ammonia* is permanent in the air, readily soluble in water, and less so in alcohol. At a high temperature it melts and sublimes; it corrodes glass, and its solution furnishes a ready means of etching upon it; it absorbs ammonia, but does not retain it when sublimed. When its solution is evaporated, ammonia escapes, and a remarkably deliquescent *bihydrofluante of ammonia*, imperfectly crystallizable, remains.

HYPONITRITE OF AMMONIA ($A + \tilde{n}$) is obtained when neutral hyp-nitrate of lead is decomposed by sulphate of ammonia. Its solution is decomposed by a very gentle heat, and evolves nitrogen; but it remains neutral. Exposed to spontaneous evaporation in a dry atmosphere, an irregularly crystallized mass is obtained, which melts, and is decomposed when heated, being resolved into nitrous oxide, water, and ammonia. (BERZELIUS.)

AMMONIA AND NITRIC ACID; NITRATE OF AMMONIA. $(n + 3h) + (n + 5o)$ or $(A + N')$. (*Hypothetical* NITRATE OF OXIDE OF AMMONIUM.) This salt may be procured by the direct union of ammonia with nitric acid; or more easily, by saturating dilute nitric acid with carbonate of ammonia. It has been mentioned as the source of *nitrous oxide*, and when carefully heated it is entirely resolved into that gas and water. Exclusive of water, nitrate of ammonia consists of

Ammonia	.	1	.	17	.	23.9
Nitric acid	.	1	.	54	.	76.1
		1		71		100.0

The decomposition of this salt by heat, and its resolution into nitrous oxide and water, furnishes a good illustration of the theory of definite proportionals, both in volumes and weights; the elements of *nitrate of ammonia* are, 2 atoms of nitrogen, 5 of oxygen, and 3 of hydrogen; and their respective *volumes* are represented in the annexed diagram.

Nitrous oxide consists of 1 proportional of nitrogen $= 14 + 1$ of oxygen $= 8$; hence the 2 proportionals of nitrogen in the salt (1 in the acid, and 1 in the ammonia) will require 2 of oxygen to produce *nitrous oxide*, and the remaining 3 of oxygen will unite to the 3 of hydrogen, to form *water*; and accordingly *nitrous oxide* and *water* are the only possible results; so that the elements after the decomposition of the salt, are arranged as in the opposite diagram:

or, represented by symbols, $(n + 5o) + (n + 3h)$ become $2(n + o)$ and $3(h + o)$.

Nitrate of ammonia has long been known, and was formerly called *Nitrum flammans*, in consequence of its rapid decomposition with a slight explosion when heated to about 600° . It differs in form according to the manner in which its solution has been evaporated; if at a temperature below 100° , its crystals are six-sided prisms terminated by six-sided pyramids; if boiled down, its crystals are thin and fibrous; it is deliquescent, and soluble in twice its weight of water at 60° , and in

its own weight at 212° . Its taste is acrid and bitter. It cannot exist without elementary water. According to Berzelius, the *prismatic* variety affords 11.232 per cent.; hence it may be considered as containing

AMIDOGEN. ($n + 2h$.) AMMONIUM. ($n + 4h$.) In the preceding notice of some of the ammoniacal salts we have considered them, in respect to the oxyacids, as similarly constituted to the metallic salts generally; ammonia appearing to act the part of a metallic oxide, and uniting to the acid to constitute a salt. But the anhydrous acids cannot thus be combined; and one atom of water is essential to the composition of all the salts of ammonia with the oxyacids. Again, we have found that when chlorine and its analogues combine with ammonia, nitrogen is evolved, and a salt is formed in which a hydracid is presumed to have united with remaining undecomposed ammonia; in short, that the same ultimate result is obtained as if ammonia and the hydracid had been directly combined, excepting that in the latter case, no evident decomposition either of the ammonia or acid has ensued. When we come to examine, in a subsequent chapter, the constitution of salts, we shall find that ammoniacal salts present other discrepancies and peculiarities when ammonia is viewed as their base, but that they may be assimilated, if ammonia be considered as the hydruret of a hypothetical base, composed of an atom of nitrogen combined with two atoms of hydrogen, and represented therefore by the symbol ($n + 2h$.) To this hypothetical body, for it has not yet been isolated, the name *amidogen*, or *ammogen*, has been given, and it is assumed that it combines in two proportions with hydrogen, forming *ammonia*, and *ammonium*; but ammonium, like amidogen, has not been separately obtained. The following, therefore, upon this hypothesis, are the compounds of nitrogen with hydrogen:—

Amidogen	{ Nitrogen . . 1 . . 14 Hydrogen . . 2 . . 2 }	or ($n + 2h$).
Ammonia	{ Nitrogen . . 1 . . 14 Hydrogen . . 3 . . 3 }	or ($n + 3h$).
Ammonium	{ Nitrogen . . 1 . . 14 Hydrogen . . 4 . . 4 }	or ($n + 4h$).

It is obvious therefore that amidogen may be considered as the direct or primary combination of nitrogen and hydrogen, and ammonia and ammonium as its two hydrurets, ammonia being ($n + 2h$) + h , and ammonium, ($n + 2h$) + $2h$.

It is assumed that in the ammoniacal salts of the oxyacids an atom of water ($h + o$) is always present, and consequently that they really are salts of oxide of ammonium, the elements of the water being concerned in converting the ammonia into oxide of ammonium; for it is clear ($n + 3h$) + $h + o$ may be regarded as ($n + 4h + o$). In

reference, therefore, to this view, nitrate of ammonia will be a nitrate of oxide of ammonium; for assuming the nitric acid to be a compound of one atom of anhydrous nitric acid and one atom of water, $(n + 5o) + (h + o)$, in which state it must be to form the salt, it is then clear that nitrate of ammonia will be $(n + 5o) + (n + 3h) + (h + o)$, and that these elements will be equivalent to $(n + 5o) + (n + 4h + o)$.

Again, as regards the combination of the hydrochloric acid with ammonia, and the supposed formation of hydrochlorate of ammonia, this salt, in reference to the preceding statement, must be regarded as a chloride of ammonium, for the elements of ammonia $(n + 3h)$ and of hydrochloric acid $(h + c)$, are equivalent to those of ammonium $(n + 4h)$ and chlorine (c) . The further illustrations of the ammonium theory, as it has been called, and the supposed proofs of the existence of amidogen will be given afterwards.

ATMOSPHERIC AIR.

THE composition of the *atmosphere* has been frequently alluded to in the preceding pages, and now that we are acquainted with its essential elements, nitrogen and oxygen, it will be useful to consider its nature and properties somewhat more in detail.

The atmosphere is a thin, transparent, invisible, and elastic fluid, which surrounds and revolves with our planet, and reaches to a considerable height above its surface, probably between forty and fifty miles.

That air is a *ponderous* body, was first suspected by Galileo, who found that a copper ball, in which the air had been condensed, weighed heavier than when the air was in its ordinary state of tension. The fact was afterwards demonstrated by Torricelli, whose attention was drawn to the subject by the attempt of a well-digger at Florence to raise water by a sucking-pump to a height exceeding 33 feet. It was then found that the *pressure of the atmosphere*, and not Nature's abhorrence of a vacuum, was the cause of the ascent of the water in the pump-pipe, and that a column of about the height mentioned, was sufficient to equipoise the atmosphere, which, at the level of the sea, presses with a weight of about *fifteen pounds on every square inch of surface*, and is capable of supporting a column of water about 34 feet high. Comparing the specific gravity of mercury with that of air and water, Torricelli inferred that if a column of air one inch square and as high as the atmosphere, weighed 15 pounds, and a column of water 34 feet high and an inch square, weighed also 15 pounds, the height of a similar column of mercury would be about 30 inches; he accordingly, in 1643, filled a glass tube, three feet long and closed at one end, with mercury, and inverted it in a basin of the same fluid; he found that the mercury fell about six inches, so that the atmosphere counterbalanced a column of *mercury* 30 inches in height. The empty space, in the upper part of the tube, has hence been called the *Torricellian vacuum*, and is nearly the most perfect that can be formed. Paschal and Torricelli afterwards observed that, upon ascending a mountain, the mercury fell in the tube, because there was less air above to press upon the surface of the metal in the basin; and thus a method of *measuring the heights of mountains by the*

barometer, as the instrument is now called, was devised. Sir Henry Englefield constructed a barometer expressly for these investigations, the mode of using which is described in the *Journal of Science and the Arts*, vol. v., p. 229. Such instruments are now commonly called *Mountain Barometers*.

The barometer indicates, by its rise and fall, a corresponding change in the pressure of the atmosphere. At the surface of the earth the *mean* density or pressure is considered equal to the support of a column of *mercury* 30 inches high, which would give a pressure upon every square inch of about 15 lbs.*

			Inches.
At 1000 feet above the surface the column falls to			28·91
2000	"	"	27·86
3000	"	"	26·85
4000	"	"	25·87
5000	"	"	24·93

2	"	"	20·29
3	"	"	16·68
4	"	"	13·72
5	"	"	11·28
10	"	"	4·24
15	"	"	1·60
20	"	"	0·95

At a height of 2·705 miles, = 11,556 feet, one volume of the atmosphere would expand into two, its calculated density being diminished at that height by one-half; the density is again halved at every 2·7 miles additional elevation, as in the following table.

Height above the sea in miles.	Volume.
0	1
2·705	2
5·410	4
8·115	8
10·820	16
13·525	32
16·230	64
18·935	128

It has been ascertained that the temperature of the atmosphere diminishes about 1° for every 350 feet of ascent, the cause of which is partly referable to the increased capacity of air for heat in proportion as its density diminishes, and partly to the circumstance that the atmosphere is chiefly heated by the earth. The line of perpetual congelation gradually descends from the equator to the poles. At 0° latitude it is stated to be 15200 feet; at 60° , 3818; and at 75° , only 1000 feet.

THE MECHANICAL PROPERTIES OF THE AIR are best illustrated by the *air-pump*, the construction of which much resembles that of the com-

* This is equal to a column of *water* of between 33 and 34 feet in height, and accordingly in all ordinary cases, the requisite length of the tube prevents the construction of *water-barometers*, but their great rise and fall, as compared with the mercurial column, and the singular facility with which they fluctuate with atmospheric changes, renders

observations with such instruments curious and instructive. A water-barometer was put up, in the year 1832, in the Hall of the Royal Society at Somerset House, under the direction of Mr. Daniell, of which an interesting description will be found in the *Philosophical Transactions* for that year.

mon pump for raising water, excepting that all the parts are more accurately and nicely made, the object being to exhaust the air as completely and expeditiously as possible. The annexed sketch (figure 242,) will give an idea of the operation of the common air-pump.

The annexed sketch (figure 242,) will give an idea of the operation of the common air-pump. *ab* are cylinders, into which the sliding-pistons *cd* are accurately fitted: *e* is a tube issuing from the bell-glass placed upon a brass plate *f*, and entering the lower part of the cylinders at *hh*, where are valves opening upwards. In each piston is also a valve opening upwards at *gg*. The cylinder *a* represents the piston in the act of being drawn up. By elevating the piston *c*, an attempt will be made to form a vacuum underneath it; but a portion of the air,

in consequence of its elasticity, will pass out of the bell *f*, along the tube *e*, and elevating the valve *h*, will fill the space below the piston, the valve *g* being kept closed by the weight of the incumbent atmosphere. In the cylinder *b* the piston is represented in the act of depression, the valve *h* therefore is forced down upon the orifice, which it perfectly closes; and the air, confined between it and the piston, now makes its escape by the piston-valve *g*, which is accordingly open, so that at every stroke of the pump a portion of air is withdrawn from the receiver *f*.

With this air-pump it is obviously impossible to obtain more than an imperfect vacuum in the receiver *f*, for the valves can only act by the elasticity of the remaining air; and, accordingly, if a barometer be placed under the receiver, the mercury will never attain a level in the tube and basin, but will always indicate a degree of pressure, as is shown by the small syphon gauge at *i*; and if a tube three feet long (*k*) have its upper end opening into the receiver, and its lower end plunged into a basin of mercury, the mercury will never rise so high as in the common barometer, where the vacuum above it is more perfect, but will indicate the pressure of a remnant of air in the receiver. The syphon gauge, and the barometer-gauge as applied at *k*, are very useful appendages to the air-pump, as showing the degree of exhaustion, and its permanence.

The operation of the pump in removing air, and the mechanical properties of the atmosphere, may be shown by a variety of experiments. Its pressure is illustrated by the force with which the bell-glass is pressed

down upon the plate of the pump; the *absence of its buoyancy*, by the descent of a guinea and a feather at the same time in the exhausted receiver; and by the preponderance of the larger of two bodies which balance each other in the open air. The *want of resistance* in the exhausted receiver is also shown by the equal duration of the motion of two fly-wheels, with their plates placed in different directions. The *elasticity* of the air is illustrated by the action of the pump itself, or by the distension which a flaccid bladder suffers during the removal of the external air, when placed under the receiver.

The extreme elasticity of the air, and the changes of bulk which it is constantly sustaining under variations of pressure and of temperature, have been already partially adverted to. The general law of its compression was originally developed by Boyle in 1662, and afterwards investigated by Mariotte. They found that the volume of air, and all other elastic fluids retaining that state, was inversely as the pressures acting upon them. Thus a volume of air = 100 under any given pressure, will be diminished to 50 when that pressure is doubled; and expanded to 200 when the pressure is diminished by one half. From the experiments of Oersted (*Edinburgh Journal of Science*, iv.), this law applies under very high pressures; indeed, till liquifaction is effected. We have, however, no evidence of the liquifaction of atmospheric air under any pressure, Mr. Perkins's experiments upon that subject (*Phil. Trans.*) not being conclusive.

SPECIFIC GRAVITY OF AIR.—The specific gravity of atmospheric air, at mean temperature and pressure, that is, the thermometer being at 60° , and the barometer at 30 inches, is usually considered as = 1, being the standard of comparison to which the specific gravities of gases and vapours are referred. In consequence of the interfering causes, and the delicacy of the methods required for the determination of the weight of a given bulk of air, the results of different experimentalists are a little at variance; and accordingly the tables of the specific gravities of æriform fluids, given in different works, are seldom exactly consistent with each other. From the latest experiments of Dr. Prout, 100 cubic inches of pure and dry atmospheric air, at mean temperature and pressure, weigh 31·0117 grains, so that, upon this datum, it is about 815 times lighter than its bulk of water, and 11,065 times lighter than its bulk of mercury. At the temperature of 32° , 100 cubic inches of atmospheric air weigh, according to Dr. Thomson, 32·79 grains. Compared with hydrogen its specific gravity is as 15·2 to 1. In the following table (drawn up by Mr. Daniell) the weight of 100 cubic inches of the lightest and heaviest known forms of matter are contrasted with air and with water in its different states: their specific gravities compared with air and water are also shown.

100 Cubic inches.	Weight in grains.	Sp. gr., air being = 1.	Sp. gr., water being = 1.
Hydrogen	2·138	0·0694	0·0000846
Air	31·000	1·0000	0·0012277
Steam	19·220	0·6240	0·0007611
Ice	23735·000	765·0000	0·9400000
Water	25250·000	814·0000	1·0000000
Platinum	542875·000	17512·0000	21·0000000

DETERMINATION OF THE SPECIFIC GRAVITY OF GASES.—For ascertaining the specific gravity of gaseous bodies, a good air-pump is essentially requisite; a light glass balloon (fig. 243) or flask *b*, and a graduated air-jar *a*, each supplied with stop-cocks, are also required. The stop-cock attached to the flask should be as small and light as possible.

Dr. Henry, in his *Elements of Chemistry*, and Mr. Faraday, in his *Chemical Manipulation*, have given explicit and extended directions for determining the specific gravities of gases, to which the reader is referred, and of which the following is an abstract.

The gases should be retained and collected over mercury, and carefully dried, by exposing them to proper substances for absorbing the aqueous vapour with which they are mixed, and which would sometimes materially affect the accuracy of the result; or they should be taken saturated with moisture, and a correction afterwards made for the weight of the vapour contained in a given bulk of the gas.

Supposing the receiver *a* to be filled with any gas, the weight of which is to be ascertained, screw the cock of the vessel *b* on the plate of an air-pump, and exhaust it as completely as possible, carefully ascertaining by the barometer-gauge of the pump, that it retains its vacuum. The weight of the exhausted vessel is then very accurately taken, even to a small fraction of a grain; and it is screwed upon the cock of the receiver *a*. On opening both cocks, the last of which should be turned very gradually, the gas ascends from the vessel *a*; and the volume which enters into the flask is known by the graduated scale on *a*. On weighing the vessel a second time, we ascertain how many grains have been admitted. If we have operated on common air, we shall find its weight to be at the rate of 31 grains to 100 cubical inches. The same quantity of oxygen gas will weigh 34·60 grains, and of carbonic acid gas 47·3 grains. In these manipulations, care is to be taken not to warm any of the vessels by contact with the hands, from which they should be defended by a glove. On opening the communication between the receiver and the exhausted vessel, if any water be lodged in the air-cock attached to the former, it will be forcibly driven into the latter, and the experiment will be frustrated. This may be avoided by using great care in filling the receiver with water, before passing into it the gas under examination: a small plug of bibulous paper, or of cotton, may also be put into the upper orifice of the stop-cock.

The specific gravity of any gas, compared with common air, is readily known, when we have once determined its absolute weight. Thus, if 100 cubic inches of air weigh 31 grains, and the same quantity of oxygen gas weigh 34·6 grains, we say,

$$31 : 34\cdot6 :: 1\cdot000 : 1\cdot111.$$

The specific gravity of oxygen gas, compared with atmospheric air, will therefore be as 1·111 to 1·000.

We may determine, also, the specific gravity of gases more simply, by weighing the flask, first when full of common air, and again when exhausted; and afterwards by admitting into it as much of the gas under

examination as it will receive, and weighing it a third time. Now, as the loss between the first and second weighing is to the gain of weight on admitting the gas, so is common air, to the gas whose specific gravity we are estimating. Supposing, for example, that by exhausting the flask it loses 31 grains, and that by admitting carbonic acid it gains 47·3; then

$$31 : 47\cdot3 :: 1\cdot000 : 1\cdot527.$$

The specific gravity of carbonic acid is, therefore, 1·527, air being taken at 1·000. And knowing its specific gravity, we can, without any further experiment, determine the weight of 100 cubic inches of carbonic acid; for, as the specific gravity of air is to that of carbonic acid, so is 31 to the number required; or

$$1\cdot000 : 1\cdot527 :: 31 : 47\cdot3.$$

100 cubic inches, therefore, of carbonic acid, will weigh 47·3 grains.

In consequence of the facility with which the bulk of aëriform bodies is altered by variations of pressure and temperature, these must always be taken into account when speaking of their respective volumes: for convenience sake, they are generally therefore reduced to what is termed *mean* pressure and temperature: *mean pressure* being that which sustains 30 inches of mercury in the barometer tube, and *mean temperature* that of 60° of Fahrenheit, or 15° of the Centigrade scale. This, at least, is by far the most convenient thermometric point, though it unfortunately happens that it is not always strictly adhered to; for by Act of Parliament, the temperature at which the specific gravity of spirituous liquors is determined for the purposes of the excise, and that at which the standard weights and measures are adjusted, is 62°.

The following are the rules for the reduction of gaseous volumes to mean pressure and temperature.

First, in respect to *pressure*, (assuming the mean height of the barometer as = 30 inches,) it is obvious that as the mean height of the barometer is to the observed height, so is the observed volume to the volume required. Suppose, for instance, we had measured 100 cubic inches of air at a barometrical pressure of 29 inches, and wished to know what would be its volume at 30 inches, we shall find by the rule of proportion that

Mean height.	Observed height.	Observed volume.	Required volume.
30	: 29	: 100	: 96·6

Or, in regard to weight, suppose that with the barometer at 29 inches, we had found 100 cubic inches of air to weigh 29·9 grains, and wished to know what the weight would be at standard pressure, we shall find by the rule of proportion that

Observed height.	Mean height:	Observed weight.	Required weight.			
29	:	30	:	29·9	:	31

Secondly, in respect to *temperature*, it has been above stated (page 142) that 100 volumes of air at 32° become 137·5 at 212°, the increase being $\frac{37\cdot5}{100}$ th of the original bulk: dividing this by 180, it is found that a volume of air dilates $\frac{1}{4\cdot80}$ th of the volume which it occupied at 32° for every degree of Fahrenheit's scale, and the same law applies to all other aëriform bodies not in contact with any liquid. If, therefore, it be re-

quired to know what volume 100 cubic inches of air at 70° would occupy at 60° , we must bear in mind that it is not $\frac{1}{480}$ th part per degree of the observed volume at 70° , which is to be deducted; but $\frac{1}{480}$ th part of the volume which 100 cubic inches at 70° would occupy at 32° . Now 480 parts of air at 32° , become 481 parts at 33° , and increase one part for every additional degree, so that at 60° they have increased to 508 parts, and at 70° to 518 parts, and thus we have a proportion between the volumes at 60° and 70° by which we can determine the question: for

Volume at 70° .		Volume at 60° .		Cub. in. at 70° .		Cub. in. at 60° .
480 + 38	:	480 + 28	:	100	:	98·069

or, on the other hand, if we wish to know the correct volume at 60° , of 40 cubic inches of air observed at 35° ,

Volume at 35° .		Volume at 60° .		Cubic inches.		Cubic inches.
480 + 3	:	480 + 28	:	40	:	42·07

Again; the weight of 100 cubic inches of air being 31 grains at 60° , the weight of an equal volume at 212° will be found as follows:—

Volume at 212° .		Volume at 60° .		Grains.		Grains.
480 + 180	:	480 + 28	:	31·0	:	23·86

In making the correction for temperature in addition to that for pressure, it matters not which is first applied to the observed volume, as the result will be the same in either case*.

It has already been observed that gas, when standing over water, becomes saturated with aqueous vapour, the quantity being proportional to the temperature. In such cases a part of the observed volume, as well as of the weight, is due to vapour, which therefore must be determined before the actual weight of the gas can be accurately calculated. The following table (FARADAY, *Manipulation*, 2nd edition, p. 376,) exhibits the proportion by volume of aqueous vapour existing in any gas standing in contact with water at the corresponding temperatures and at mean barometric pressure.

By reference to this table, which is founded upon the experiments of Mr. Dalton and Dr. Ure, and includes any temperature at which gases

* I have taken the above equations from Mr. DANIELL'S *Introduction* (§ 154) upon the subject: the rule is frequently misunderstood and therefore misstated. to which I refer for further remarks

are likely to be weighed, the proportions in bulk of vapour present, and consequently of the dry gas, may be easily ascertained. For this purpose the observed temperature of the gas should be looked for, and opposite to it will be found the proportion in bulk of aqueous vapour at a pressure of 30 inches. The volume to which this amounts should be ascertained and corrected to mean temperature. Then the *whole* volume is to be corrected to mean temperature and pressure, and the corrected volume of vapour subtracted from it. This will leave the corrected volume of dry gas. It has been ascertained, in a manner approaching to perfect accuracy, that a cubic inch of permanent aqueous vapour corrected to the temperature of 60° , and a mean pressure of 30 inches, weighs 0.1929 grains. The weight, therefore, of the known volume of aqueous vapour, is now easily ascertained, and this being subtracted from the weight of the moist gas, will give the weight of the dry gas, the volume of which is also known. As an illustration, suppose a gas standing over water had been thus weighed, and that 220 cubic inches at the temperature of 50° Fahr., and barometric pressure of 29.4 inches had entered into the globe and caused an increase in weight of 101.69 grains. By reference to the table it will be found that at the temperature of 50° , the proportion of aqueous vapour in gas standing over water is .01333, which in the 220 cubic inches will amount to 2.933 cubic inches, which, corrected to the temperature of 60° , becomes 2.942 cubic inches. The whole volume corrected to mean temperature and pressure will be found to equal 219.929 cubic inches, from which, if the 2.942 cubic inches of aqueous vapour present be subtracted, it will leave 216.987 cubic inches as the volume of *dry* gas at mean temperature and pressure: 2.942 cubic inches of aqueous vapour weigh .5675 grains, for $2.942 \times 0.1929 = 0.5675$; this subtracted from 101.69, the whole weight leaves 101.1225 grains, which is the weight of the 216.917 cubic inches of dry gas; and by the simple rule of proportion, therefore, it will be found that 100 cubic inches of such gas, when dried, and at mean temperature and pressure, will weigh 46.603 grains.

Mr. Daniell (*Introduction*, § 203) gives the following data for calculating the amount of the correction for moisture. "Suppose we found 100 cubic inches of a gas saturated with vapour, properly corrected for the temperature of 60° , and 30 inches pressure, to weigh 31 grains, and wished to know the equivalent bulk and weight of the dry gas. The observed volume is partly due to the expansion occasioned by the vapour, and this portion will be in the same proportion to the whole as the elasticity of the vapour is to the total elasticity: therefore,

Barom. pressure.	Force of vap. at 60° .	Cubic inches.	Cubic inches.
30.000	: 0.560	: : 100	: 1.86

The volume of the dry gas is therefore $100 - 1.86 = 98.14$ cubic inches. Now this expansion of 1.86 cubic inches may be regarded as so much vapour of the same elasticity as the air diffused through the whole space; and as the specific gravity of such steam compared to air is as 0.620 to 1.000, then

Sp. Gr. of Air.	Sp. Gr. of Steam.	Grains.	Grains.
1	: 0.620	: : 31	: 19.22 = weight of 100 cubic inches of steam;

	Cubic inches.		Grains.		Cubic inches.		Grains.
and	100	:	19.22	:	1.86	:	0.35

which gives the weight of the vapour to be deducted from the total weight: making the weight of 98.14 cubic inches of dry air = $31 - 0.35$ or 30.65.

When it is required to deprive gases of vapour, so as to render them *dry*, they may be slowly passed through a tube about half an inch diameter, and from two to three feet long, containing fragments of fused and dry chloride of calcium, which, by its strong attraction for moisture, effects the desiccation of the gas. A few gases are, however, absorbed by it, in which case fused potassa, or fused carbonate of potassa, duly comminuted, may be substituted. Some gases are conveniently dried by exposing them to a surface of sulphuric acid. (See FARADAY'S *Manipulation*, p. 386.)

COMPOSITION OF THE ATMOSPHERE.—Atmospheric air has already been stated to consist essentially of oxygen and nitrogen: these gases are merely in a state of mechanical mixture, and by no means, as some have supposed, in chemical combination. There are various ways of learning the proportion which the oxygen bears to the nitrogen; and as the relative fitness of the air for breathing has sometimes been considered as depending upon the quantity of oxygen contained in a given volume, the instruments used in these experiments have been called *eudiometers*.

From facts already stated, it is obvious, that if atmospheric air, mixed with a certain quantity of *hydrogen*, be detonated by the electric spark, the absorption will be proportionate to the quantity of oxygen present. When 100 measures of pure hydrogen are mixed with 100 of pure oxygen, the diminution of bulk after detonation will amount to 150 parts; that is, one volume of oxygen condenses two of hydrogen. If we introduce into the graduated detonating tube (fig. 230) 300 measures of common air, and 200 of pure hydrogen, there will remain, after detonation, 314 measures; so that 186 measures will have disappeared, of which one-third may be estimated as pure oxygen: hence 300 parts of air have thus lost 63 of oxygen, or 21 *per cent*.

The general rule, therefore, for estimating the purity of air by hydrogen gas may be stated as follows:—Add to 3 measures of the air under examination 2 measures of pure hydrogen; detonate; and, when the vessel has cooled, observe the absorption; divide its amount by 3, and the quotient is the quantity of oxygen.

This mode of ascertaining the proportion of oxygen in atmospheric air, by detonation with hydrogen, was first resorted to by Volta, and is susceptible of great accuracy, since hydrogen is easily procured almost absolutely pure. An improved detonating tube for these purposes has been described by Gay Lussac. (*Ann. de Chim. et Phys.*, iv. 188.) The simplest form of instrument, however, for detonating gaseous mixtures, is that contrived by Dr. Ure; it consists of a glass syphon with legs nearly of equal length, open and slightly funnel shaped at one extremity, and hermetically sealed and supplied with platinum detonating wires at the other. The sealed leg is graduated by introducing successively equal weights of mercury from a glass measure; 7 ounces and 66 grains troy

occupy the space of a cubic inch, and 34·25 grains represent $\frac{1}{100}$ of that volume. To use this instrument, it is filled with mercury, and inverted in the pneumatic trough; a convenient quantity of the gaseous mixture is introduced, and having applied a finger to the orifice, the tube is removed and inverted so as to transfer the gas to the sealed leg, where its quantity is very accurately measured; we then pour a portion of mercury from the open end of the tube, so as to leave a space of about two inches, and closing the aperture with the thumb, detonate by the electric spark: the included portion of air serves as a spring, and, on withdrawing the thumb, the change of bulk is read off, having previously added mercury, so as to bring it to a level in both legs of the syphon. Any liquid or solid that is required, may then be passed up into the closed end for the analysis of the residuary gas. (*Edin. Phil. Trans.*, 1818.)

The action of *spongy platinum*, already mentioned (p. 386), may be resorted to, to effect the union of oxygen and hydrogen in eudiometrical experiments; or, the air under examination may be mixed with its bulk of pure hydrogen, and two or three of the small balls, composed of spongy platinum and clay, thrown up into the mixture standing over mercury; in the course of an hour or two, when the diminution of bulk has attained its maximum, and the vessel has cooled, the residuary gas is carefully measured, and one-third of its loss of bulk is = to the oxygen.

Scheele, in his eudiometrical experiments, employed *sulphuret of potassium*, the solution of which absorbs oxygen, as may be shown by agitating it with atmospheric air in a graduated glass tube. In this experiment the nitrogen remains unaltered. The *eudiometric tubes* of Dr. Hope (*Nicholson's Journal*, vol. iv.) and Dr. Henry (*Elements*, vol. i. p. 149), as represented in the marginal wood-cuts (fig. 244 and 245), are convenient for such experiments by absorption. The former consists of a small bottle, holding about three ounces, into which the graduated glass tube *a* is carefully fitted by grinding. It also has a ground stopper at *b*.

244

245

To use it, the phial is filled with the solution of the alkaline sulphuret, and the tube *a*, containing the air to be examined, fitted into its place. After inverting and agitating the instrument, the stopper *b* may be opened under water, and the absorption is shown by the rise of the fluid in the tube. For the glass-bottle, Dr. Henry substituted the elastic gum-bottle *b* (fig. 245), in the neck of which a short piece of glass tube is secured, into which the tube *a* is fitted by grinding. In the *Philosophical Transactions* for 1807, Mr. Pepys has described a modification of this eudiometer, which may be often advantageously employed in delicate experiments, and by which an absorption of a thousandth part of the gas under examination may be measured.

When *nitric oxide gas* and atmospheric air are mixed, there is a production of nitrous acid, in consequence of the union of oxygen with the oxide; and if the mixture be made over water, an absorption proportional

to the quantity of nitrous acid formed ensues. Upon this principle nitric oxide may be used in eudiometrical experiments; and, if proper precautions be attended to, it furnishes tolerably accurate results. Priestley and Cavendish, (*Phil. Trans.*, 1783,) availed themselves of this mode, and Dalton has offered some remarks upon its relative accuracy (*Phil. Mag.*, vol. xxviii.) The most certain results are obtained by adding to 100 parts of the atmospheric air, previously introduced into a small beer-glass, an equal volume of nitric oxide gas. The mixture may be gently agitated, and in two or three minutes carefully decanted into a graduated tube, when it will be found, provided the nitric oxide be pure, that 84 measures have disappeared: of which one-fourth, or 21 measures, are oxygen. Sir H. Davy suggested the use of a *solution of protosulphate of iron, impregnated with nitric oxide gas*, for the absorption of oxygen; it may be employed in the same way as the alkaline sulphuret.

If a stick of *phosphorus* be confined in a portion of atmospheric air, it will slowly absorb the oxygen present. The rapid combustion of the same substance may also be conveniently resorted to. For this purpose a small piece of phosphorus may be introduced into the bulb of the tube *a* (fig. 246), containing a given measure of the air to be examined, confined over mercury, which, to prevent loss by expansion, should be suffered to occupy about half the tube, or to stand at *b*. The phosphorus may then be inflamed, and distilled through the air in the tube; and when the combustion is over, and the tube cold, the residuary air may be transferred for measurement. These eudiometrical methods were used by Lavoisier, Berthollet, and Seguin, (*Annales de Chimie*, tom. ix. and xxxiv.,) and are both susceptible of accuracy; and a loss of volume, nearly = 21 per cent. of the atmospheric air, will invariably be found to have occurred.

Lastly, Gay Lussac has recommended the use of slips of copper moistened with hydrochloric acid, for the removal of oxygen from the air; Saussure has used thin turnings of clean metallic lead, which when agitated with a little water in the contact of air, absorbs its oxygen, and forms hydrated oxide of lead: and Berzelius employs the liquid amalgam of lead and mercury for the same purpose. Of these various processes, detonation with, or absorption by, hydrogen, and the action of burning phosphorus, are those which are usually resorted to, and are most precise and easily performed.

By experiments thus conducted, it has been found that the composition of the atmosphere is extremely uniform in all parts of the world, and at all heights above its surface; and it has generally been considered as consisting of

	By Measure.	By Weight.
Oxygen . . .	21	23
Nitrogen . . .	79	77
	<hr/> 100	<hr/> 100

Though these are what are usually termed the *essential* component parts of atmospheric air, it contains other substances, which to a certain

extent may be regarded as adventitious, and the quantity of which is liable to vary*: of these, *carbonic acid and aqueous vapour* are the most important and constant. The quantity of the former may usually be considered as amounting to less than about $\cdot 01$ per cent.† The presence of *aqueous vapour* in the atmosphere is shown in a variety of ways, but most easily by exposing to it certain deliquescent substances, which liquify or increase in weight in consequence of its absorption; and as the gases in general, unless artificially dried, also contain vapour of water, it is necessary, in delicate experiments, and in ascertaining their specific gravity, to take this ingredient into the account (see p. 443), or to separate it by proper means, such as exposure to very deliquescent substances, among which fused chloride of calcium is especially useful, under the precautions already mentioned.

The quantity of water contained in air and gases is subject to variation. From the experiments of Saussure, Dalton, and Ure, already referred to, it appears that 100 cubic inches of atmospheric air at 57° , are capable of retaining 0.35 grains of watery vapour; in this state the air may be considered at its maximum of humidity; it would also appear that all the gases take up the same quantity of water when under similar circumstances, and that it consequently depends, not upon the density or composition, but upon the bulk of the gaseous fluid; and from Dalton's researches, already mentioned, it may be concluded that the vapour forms an independent atmosphere, mixed, but not combined with the air. (See DANIELL'S *Meteorology*.)

Hygrosopes and hygrometers are instruments which show the presence of water in the air, its variation in quantity, and its actual quantity existing in a given bulk of air at any given time. Saussure employed a human hair, which, by its dilatations and contractions in moisture and dryness, turned an index; Deluc used a thin strip of whalebone in the same way; Wilson employs a rat's bladder, filled with mercury, and tied on to a large thermometer-tube; by its dilatation and contraction the mercury falls and rises in the tube, and thus indicates changes in the moisture of the air. Dr. Mason's hygrometer shows the relative

* Lavoisier's experiments gave 27 measures of oxygen and 73 nitrogen: Priestley stated the oxygen to vary from 20 to 25 *per cent.*: Cavendish estimated it at 20 *per cent.*: Berthollet found in the air of Cairo and of Paris 22 of oxygen: Saussure in Geneva 21 to 22: De Marty in Catalonia, in all situations, 21 to 22; Davy, at Bristol and upon the west coast of England, during westerly winds, 21. The same in air from the coast of Guinea. Berger on the Jura, and on the mountains and in the valleys of Savoy, 20.3 to 21.6: Configliachi on the Simplon 21, and in the Rice-fields of the Milanese 20.8: Gay Lussac, 22,000 feet above the surface, and in Paris, 21.49: Dalton in England 20.7 to 20.8: seldom 21; but on Jan. 8, 1825, Barom. 30.9 and wind north east, 21.15. Gay Lussac and Humboldt,

instead of 21, as in the external air, found 20.2 in the Théâtre François during the performance. (L. GMELIN, *Handbuch*, i. 443.)

† Saussure and Gay Lussac found the usual proportion of carbonic acid in the air from the summit of Mont Blanc, and 650 toises above Paris. Beauvais found scarcely a trace of carbonic acid in the air over the sea off Dieppe, but the usual proportion inland. According to Saussure the proportion varies with the season: the air in a meadow, in August, contained 0.000713; in Jan., 0.000479; in Nov., in rainy and stormy weather, 0.000425. Dalton estimates the carbonic acid at 0.001; Configliachi the maximum at 0.008, and Humboldt (probably an excess) at 0.005 to 0.018. (L. GMELIN.)

dryness and moisture of the atmosphere by the degree of cold produced by evaporation from a given surface. If two delicate thermometers have their bulbs covered with a thin piece of muslin, and if the one be dry and the other moist, the depression of the latter will be directly as the rapidity or amount of evaporation, and this again will chiefly depend upon the state of the circumambient air as to moisture: if it be charged with vapour, no evaporation from the wet bulb will ensue, and consequently the mercury in that thermometer will remain stationary: if, on the contrary, it be very dry, it will eagerly abstract vapour from the humid surface, and a corresponding degree of cold will be indicated by the depression of the mercury in the humid thermometer, as compared with the standard or dry thermometer. The annexed wood-cut shows the arrangement of the thermometers in Dr. Mason's instrument. He covers the bulbs with white silk, and that intended for the hygrometric indications is kept constantly moist by the capillary action of a thread of floss silk which is attached to it, and of which one end dips into the cup of water forming the lower end of a reservoir, which acts upon the principle of the bird fountain. In this instrument the hygrometric degrees are best expressed by those of the thermometric scale.

Mr. Daniell's hygrometer shows the constituent temperature of the moisture in the atmosphere, by its precipitation upon a cold surface; comparing this with the temperature of the atmosphere, the difference furnishes a datum for calculating the quantity of vapour in a given quantity of air. A detailed account of this instrument, and of the observations made with it, is given by Mr. Daniell in the *Quarterly Journal of Science* (vols. viii. ix. and x.), and in his "Essays." It consists of a tube, twice bent at right angles, at the ends of which are two thin glass bulbs; the one tightly covered by a piece of fine muslin, the other about half full of ether, and including a very delicate thermometer, the small oblong bulb of which is immersed into the ether, as shown in fig. 248. The bulbs and tubes are filled with the vapour of ether, to the entire exclusion of air, so that when the instrument is placed as in the figure, and the bulb *a* is cooled by dropping a few drops of good ether upon it, (see page 183 in reference to the phenomena of evaporation, and the construction of the cryophorus, which acts upon the same principle,) the interior ethereal vapour is in part condensed, and the liquid in *b* furnishes a fresh portion, by which its temperature is more or less lowered, as shown by the immersed thermometer *d*. Now when the bulb *b* is thus cooled, it is in the condi-

tion of any other cold body, and has a tendency to cause the deposition

of aërial moisture upon its surface; and the temperature at which such deposition will take place, or in other words the *dew-point*, will vary with the hygrometric state of the air. In very humid atmospheres the thermometer *d* will scarcely have fallen a degree before a ring of moisture is evident upon *b*, coinciding with the surface of the included ether, and being the point of lowest temperature: in dry atmospheres, on the other hand, it will be necessary to reduce the temperature of the included thermometer, by the continuous evaporation of ether from the covered bulb, many degrees, before the ring of dew is visible. Now the temperature at which this ring of dew is deposited, or the *dew-point*, may be accurately read off upon the interior thermometer by observing the degree at which it stands, *at the*

moment of the first appearance of the ring of dew; and this observation may be corrected or verified by again observing the temperature or degree at which *the ring of dew vanishes*: these two observations seldom differ more than a degree or two, and the mean may be assumed as correct, for the errors, if any, must lie in opposite directions. There is a second or external thermometer attached to this instrument at *k*, which shows the temperature of the air at the time of making the observation; and the difference between the two thermometers at that time gives the exact temperature required for the deposition of the aërial moisture, or is the dew-point; the extent of this difference is as the dryness of the air, and may thus be used as an hygrometric term. On one day, for instance, the external thermometer being 60° , the internal fell to 48° before the ring of dew appeared: on another day the external thermometer stood at 66° , and the internal had only fallen to 64° when the dew-ring appeared; here therefore the degree of dryness might be called 12° in the former, and 2° in the latter case. It is obvious then, in regard to this instrument, that it furnishes a very ready and exact method for the determination of the *dew-point*.

“By means of the dew-point accurately ascertained,” Mr. Daniell observes, “many points of the utmost interest to chemical and meteorological science may be determined. By mere inspection of tables properly constructed, we can at once determine the elasticity and density of the aqueous vapour—its weight in a cubic foot of the air—the degree of dryness either upon the thermometric or the hygrometric scale—and the rate of evaporation; when the air is saturated, the precipitation is instantaneous, *i.e.*, the dew-point coincides with the temperature of the air.

In this country, the degree of dryness measured in thermometric degrees seldom reaches 30° , that is to say, the dew-point is seldom 30° below the temperature of the air, but in the Deccan, with a temperature of 90° , the dew-point has been seen as low as 29° , making the degree of dryness 61° .

"The more accurate mode, however, of expressing the moisture of the air from an observation of the temperature and dew-point, is by the quotient of the division of the elasticity of vapour at the real atmospheric temperature, by the elasticity at the temperature of the dew-point: for, calling the term of saturation 1000, as the elasticity of vapour at the temperature of the air is to the elasticity of vapour at the temperature of the dew-point, so is the term of saturation to the observed degree of moisture. Thus, with regard to the observation in the Deccan,

$$1.430 : 0.194 :: 1000 : 135.$$

"The fourth term is the degree of moisture on the hygrometric scale."

As an average of results, the ordinary constituents of the atmosphere appear to be in the following proportions:

	By Measure.	By Weight.
Nitrogen	77.5	75.55
Oxygen	21.	23.32
Aqueous vapour	1.42	1.03
Carbonic acid	0.08	0.10
	100	100

If the relative bulk of oxygen to nitrogen be considered as 1 to 4, and many analysts will not allow that the atmosphere contains more than 20 of oxygen to 80 of nitrogen, it follows that, in reference to the atomic theory, it is a mixture of one proportional of oxygen = 8, and two of nitrogen = $14 \times 2 = 28$; which may be thus represented:—

Oxygen. 8	=	Atmospheric Air.
Nitrogen. 14		
Nitrogen. 14		

In addition to the substances above enumerated as the *constant* component parts of our atmosphere, it contains, in certain situations, minute quantities of what may be termed *accidental ingredients*, the nature and proportions of which depend upon a variety of causes; and "as the sea contains a little of everything that is soluble in water, so," as Dr. Prout observes, "the atmosphere may be conceived to contain a little of everything that is capable of assuming the gaseous form." It has even been supposed that all substances may impart in this way portions of foreign matter, which, though infinitely small, would in time accumulate into sensible proportions; the formation of *aërolites* has even been referred to such a cause: but the fallacy of this hypothesis has been satisfactorily demonstrated by Faraday (*On the existence of a limit to vaporisation*, *Phil. Trans.*, 1826, p. 484), his argument being founded on the principle by which Dr. Wollaston accounted for the limited extent of the atmosphere (*Phil. Trans.*, 1822, p. 89); namely, that its boundary is dependent upon the opposing powers of elasticity and gravitation. On passing

upwards from the earth's surface the air becomes more and more attenuated in consequence of the gradually diminishing pressure of the superincumbent part, and its tension or elasticity is proportionately diminished: when the diminution is such that the elasticity is a force not more powerful than the attraction of gravity, then a limit to the atmosphere must occur: the particles of the atmosphere there tend to separate with a certain force, but this force is not greater than the attraction of gravity which tends to make them approach the earth and each other; and as expansion would necessarily give rise to diminished tension, the force of gravity would then be strongest, and consequently cause contraction, until the powers were balanced as before.

This condition of ærial particles, Mr. Faraday applies to all other vapours, and infers that every kind of matter ceases to assume the elastic form, when the gravitation of its particles exceeds the elasticity of its vapour; and by proving that a variety of substances, kept for some years in a confined space and with moisture, underwent no evaporation, he has furnished ample grounds for denying the existence of a miscellaneous collection of vapours in the atmosphere.

To revert, however, to the *extraneous matters*, as they may be called, which have actually been detected, or may fairly be presumed to exist at times in the air. We observe, in London, that traces of sulphurous and sulphuric acid are observable, and also of sulphate of ammonia, which salt we sometimes see upon dirty windows in small stellated spots: these, as well as finely-divided carbonaceous matter, are no doubt derived from coal-smoke. In the same way the air in the vicinity of certain manufactories, reducing-furnaces, and other places where large quantities of peculiar gases or vapours may be generated, will be liable to more or less *local contamination*. In the vicinity of the sea, and especially during storms, the rain which falls contains traces of salt, and during a thunder-storm it may possibly afford slight indications of nitric acid (p. 325). Sometimes rain and snow have been coloured by extraneous matters, mechanically diffused through the air; this has occasionally been traced to minute lichens, and other cryptogamous plants, brought from a distance by the winds, and diffused in myriads through the atmosphere; and sometimes to volcanic dust composed of earthy and metallic matters in a state of extreme comminution. The substances foreign to our atmosphere, and held in it in what may be termed a state of solution, are probably more numerous and various, though little understood, and from their nature, and the minute quantities in which they exist, very difficult of detection or examination. Various forms of *infection*, and *malaria* or *marsh-miasma*, are instances of such contaminations, and it is not improbable, from the manner in which they appear to be decomposed and destroyed by chlorine, that they consist of some hydrogenated compounds. Dr. Prout (*Bridgewater Treatise*, p. 350,) has suggested the possibility of some form of selenium being occasionally present in the air, so as to produce catarrhal epidemics, and in favour of the production of diseases by some such foreign matters, adduces the following observations which occurred to him during the presence of the epidemic cholera. "He had for some years been occupied in investigations regarding the atmosphere, and for more than six weeks previous to the appearance of

cholera in London, had almost every day been engaged in endeavouring to determine with the utmost possible accuracy the weight of a given quantity of air, under precisely the same circumstances of temperature and pressure. On a particular day, the 9th of February, 1832, the weight of the air suddenly appeared to rise above the usual standard. As the rise was at the time supposed to be the result of some accidental error, the succeeding observations were made with the most rigid scrutiny. On the days immediately following, the weight of the air still continued above the standard, and retained its augmented weight during the whole time the experiments were carried on, namely, about six weeks longer: the increase of weight was small, but still decided and real." Dr. Prout then goes on to state, that on the 9th of February the wind, which had been previously west, veered round to the east, and that precisely on the change of the wind, the first cases of the epidemic cholera were reported in London, and that from that time the disease continued to spread. I bring forward these observations not only as curious in themselves, but as showing, at least one cause of a possible discrepancy in the different estimates of the specific gravity of atmospheric air.

It has already been remarked, that in all common cases of combustion in atmospheric air, the oxygen enters into new combinations, whilst the nitrogen remains passive. In the same way, in the function of respiration, a portion of the oxygen is converted into carbonic acid, and is expired along with the unaltered nitrogen. This constant consumption of oxygen has induced theorists to seek for some method of its restitution in a pure state to the atmosphere; and Dr. Priestley suggested the functions of the vegetable creation as one source of such renovation. But it appears from the calculations of De Saussure, that in these inquiries the enormous bulk or quantity of the atmosphere has been forgotten, and that the united effect of the different deteriorating processes would not occasion any sensible difference in the chemical composition of the whole mass for many hundred years. In these speculations it must always be remembered that the different parts of the atmosphere are constantly kept in a uniform state of mixture, by the propensity which gaseous bodies have, notwithstanding material differences in their specific gravities, to diffuse themselves equably through each other, and that this equality of mixture is further promoted by the constant agitation to which the air is subjected by winds, and by the varied temperature of different portions of the earth's surface.

The combustion of substances in the air under ordinary circumstances will be explained, by reference to the details given in the chapter on Oxygen (p. 360). Some peculiar cases of combustion, however, which require more extended notice, have been ingeniously investigated by Sir H. Davy (*Essay on Flame*, and *Phil. Trans.*, 1817). In examining the effect of *rarefaction* upon combustion, he found that when hydrogen gas was inflamed at a fine orifice, so as to make a jet of flame of about one-sixth of an inch in height, and introduced under the receiver of an air-pump containing from 200 to 300 cubical inches of air, the flame enlarged as the receiver became exhausted; and when the gauge indicated a pressure between four and five times less than that of the atmosphere, was at its maximum of size; it then gradually diminished below, but

burned above, till the pressure was between seven and eight times less, when it became extinguished.

To ascertain whether the effect depended upon the deficiency of oxygen, he used a larger jet with the same apparatus, when the flame burned longer, and this when the atmosphere was rarefied ten times. When the larger jet was used, the point of the glass tube became white-hot, and continued red-hot till the flame was extinguished. It therefore occurred to him, that the heat communicated to the gas by this tube, was the cause that the combustion continued longer in the last trials when the larger flame was used; and the following experiments confirmed the conclusion. A piece of wire of platinum was coiled round the top of the tube, so as to reach into and above the flame. The jet of gas of one-sixth of an inch in height was lighted, and the exhaustion made; the wire of platinum soon became white-hot in the centre of the flame, and a small point of wire near the top fused; it continued white-hot till the pressure was six times less; when it was ten times less it continued red-hot at the upper part, and as long as it was dull red, the gas, though extinguished below, continued to burn in contact with the hot wire, and the combustion did not cease until the pressure was reduced thirteen times.

It appears from this result, that the flame of hydrogen is extinguished in rarefied atmospheres, only when the heat it produces is insufficient to keep up the combustion, which appears to be when it is incapable of communicating visible ignition to metal, and as this is the temperature required for the inflammation of hydrogen at common pressures, it appears that its *combustibility* is neither diminished nor increased by rarefaction from the removal of pressure.

According to this view with respect to hydrogen, it should follow that, amongst other combustible bodies, those which require least heat for their combustion ought to burn in more rarefied air than those that require more heat; and those that produce much heat in their combustion ought to burn, other circumstances being the same, in more rarefied air than those that produce little heat; and Sir Humphry's experiments confirm these conclusions. Thus, olefant gas, which approaches nearly to hydrogen in the heat produced by its combustion, and which does not require a much higher temperature for its inflammation, when its flame was made by a jet of gas from a bladder connected with a small tube furnished with a wire of platinum, under the same circumstances as hydrogen, ceased to burn when the pressure was diminished between ten and eleven times; and the flames of alcohol and of a wax-taper, which require a greater consumption of heat for the volatilization and decomposition of their combustible matter, were extinguished when the pressure was five or six times less without the wire of platinum, and seven or eight times less when the wire was kept in the flame. Light carburetted hydrogen, which produces less heat in combustion than any of the common combustible gases, except carbonic oxide, and which requires a higher temperature for its inflammation than any other, had its flame extinguished, even though the tube was furnished with the wire, when the pressure was below one-fourth.

The flame of carbonic oxide, which, though it produces little heat in

combustion, is as inflammable as hydrogen, burned when the wire was used, the pressure being one-sixth.

The flame of sulphuretted hydrogen, the heat of which is in some measure carried off by the sulphur produced by its decomposition during its combustion in rare air, when burned in the same apparatus as the olefiant and other gases, was extinguished when the pressure was one-seventh.

Sulphur, which requires a lower temperature for its combustion than any common inflammable substance, except phosphorus, burned with a very feeble blue flame in air rarefied fifteen times, and at this pressure the flame heated a wire of platinum to dull redness, nor was it extinguished till the pressure was reduced to one-twentieth*.

Phosphorus, as has been shown by M. Van Marum, burns in an atmosphere rarefied sixty times; and Sir Humphry found that phosphuretted hydrogen produced a flash of light when admitted into the best vacuum that could be made by an excellent pump of Nairn's construction.

The mixture of chlorine and hydrogen inflames at a much lower temperature than that of hydrogen and oxygen, and produces a considerable degree of heat in combustion: it was therefore probable that it would bear a greater degree of rarefaction, without having its power of exploding destroyed; and this was found by many trials to be actually the case, contrary to the assertion of M. de Grotthus. Oxygen and hydrogen, in the proportion to form water, will not explode by the electrical spark when rarefied eighteen times; but hydrogen and chlorine in the proportion to form hydrochloric acid gas, gave a distinct flash of light under the same circumstances, and they combined with visible inflammation when the spark was passed through them, the exhaustion being to one-twenty-fourth.

The experiment on the flame of hydrogen with the wire of platinum, and which holds good with the flames of the other gases, shows, that by preserving heat in rarefied air, or giving heat to a mixture, inflammation may be continued, when, under common circumstances, it would be extinguished. This was found to be the case in other instances, when the heat was differently communicated: thus, when camphor was burned in a glass tube, so as to make the upper part of the tube red-hot, the inflammation continued when the rarefaction was nine times, whereas it would only continue in air rarefied six times, when it was burned in a thick metallic tube which could not be considerably heated by it. (DAVY on *Flame*, p. 56.)

The influence of the admixture of other gases with atmospheric air upon its power of supporting combustion, is another subject which has been elucidated by Sir H. Davy's experiments. He found that a wax-

* The temperature of the atmosphere diminishes in a certain ratio with its height, which must be attended to in the conclusions respecting combustion in the upper regions of the atmosphere, and the elevation must be somewhat lower than in arithmetical progression, the pressure decreasing in geometrical progression. There is, however, every reason to believe that the taper would be extinguished at a height of between 9 and 10 miles, hydrogen between 12 and 13, and sulphur between 15 and 16.

taper was instantly extinguished in air mixed with one-tenth of silicated fluoric acid gas, and in air mixed with one sixth of hydrochloric acid gas; but the flame of hydrogen burned readily in those mixtures; and in mixtures in which the flame of hydrogen was extinguished the flame of sulphur burned.

The following simple experiment demonstrates this general principle. Into a long bottle with a narrow neck introduce a lighted taper, and let it burn till it is extinguished; carefully stop the bottle, and introduce another lighted taper; it will be extinguished before it reaches the bottom of the neck; then introduce a small tube containing zinc and diluted sulphuric acid, at the aperture of which the hydrogen is inflamed; the hydrogen will be found to burn in whatever part of the bottle the tube is placed: after the hydrogen is extinguished, introduce lighted sulphur; this will burn for some time; and after its extinction, phosphorus will be as luminous as in the air, and, if heated in the bottle, will produce a pale-yellow flame of considerable density.

In cases when the heat required for chemical union is very small, as in the instances of hydrogen and chlorine, a mixture which prevents inflammation will not prevent combination, *i. e.*, the gases will combine without any flash. Thus, in mixing two volumes of carburetted hydrogen with one of chlorine and hydrogen, hydrochloric acid was formed throughout the mixture, and heat produced, as was evident from the expansion when the spark passed, and the rapid contraction afterwards, but the heat was so quickly carried off by the quantity of carburetted hydrogen that no flash was visible.

Steam, and such vapours as require considerable heat for their formation, have a less power of preventing combustion than permanent gases. Sir H. Davy found that a very large quantity of steam was necessary to prevent sulphur from burning. Oxygen and hydrogen exploded by the electric spark, when mixed with five times their volume of steam; and even a mixture of air and carburetted hydrogen gas, the least explosive of all mixtures, required a third of steam to prevent its explosion; whereas one-fifth of nitrogen produced the effect. (DAVY on *Flame*, p. 87.)

In the course of the above experiments, Sir Humphry endeavoured to ascertain what would be the effect of condensation on flame in atmospheric air, and whether the cooling power of the nitrogen would increase in a lower ratio, as might be expected, than the heat produced by the increase of the quantity of matter entering into combustion. He found considerable difficulties in making the experiments with precision; but he ascertained that both the light and heat of the flames of the taper, of sulphur, and of hydrogen, were increased in air condensed four times, but not more than they would have been by an addition of one-fifth of oxygen.

He condensed air nearly five times, and ignited iron-wire to whiteness in it by the Voltaic apparatus, but the combustion took place with very little more brightness than in the common atmosphere, and would not continue as in oxygen; nor did charcoal burn much more brightly in this compressed air than in common air. These experiments show that (for certain limits at least), as rarefaction does not diminish considerably the

heat of flame in atmospheric air, so neither does condensation considerably increase it; a circumstance of great importance in the constitution of our atmosphere, which at all the heights or depths at which man can exist, still preserves the same relations to combustion.

§ VIII. SULPHUR.

SULPHUR, or *brimstone*, is a brittle substance, of a pale-yellow colour, somewhat translucent, insipid, and inodorous, but exhaling a peculiar odour when heated. The ancients used it in medicine, and its fumes were employed in bleaching wool. (PLINY, lib. xxxv. cap. xv.) Its specific gravity is 1.970, to 2.080. Its specific heat, as determined by Regnault, is 0.20259; by Dulong and Petit, 0.1880. It becomes negatively electrical by heat and by friction, and is a non-conductor of electricity*.

Sulphur is chiefly a mineral product, and occurs crystallized, its primitive form being an acute octoëdron with a rhombic base. These crystals are in a high degree doubly refractive. According to Mitscherlich, it has, when artificially crystallized, as when suffered gradually to cool after having been fused, a different primitive form, namely, an oblique rhombic prism. From its solutions in alcohol, ether, sulphuret of carbon, and chloride of sulphur, it is generally deposited in the octoëdral form. Crystals of native sulphur which have been formed by the condensation of sulphur vapour, as well as those which are deposited from a solution of sulphur in any menstruum, possess forms which are either identical, or connected by being referable to the same crystalline axes. Such, on the contrary, as are produced by the cooling of fused sulphur belong to a different system of crystallization. The condition determining the form is temperature: if the crystal be formed below 232° it belongs to the right prismatic system; if at that point, to the oblique prismatic. This is proved by the influence of temperature on a crystal of either system; a crystal of fusion, when first formed, is perfectly clear and transparent, but kept at common temperatures it soon becomes opaque, and presents the appearance of the roll-sulphur of commerce: the same change occurs when a native crystal is placed in a solution of salt which boils at 232° . The opacity is in both cases produced by a new arrangement of the particles of sulphur, by which, without any change in the exterior form, the internal structure of the crystal is altered to correspond to the crystallization peculiar to the temperature.

Native sulphur is principally brought to this country from Sicily, where it occurs in beds, in a blue clay formation, occupying the central half of

* Sulphur, in its ordinary state, always contains traces of hydrogen, which it gives off during the action of various bodies for which it has a powerful attraction. Thus, if equal weights of sulphur and copper, or iron-filings, be introduced into a retort, and heated, a portion of sulphuretted hydrogen is evolved at the period of their combination. When potassium and sulphur are heated together, a vivid combustion ensues, and a little sulphuretted hydrogen is evolved. Berzelius, by heating sulphur with oxide of lead, remarked the formation of water, but in such small and indefinite quantities, as induced him to adopt the generally received opinion, that the presence of hydrogen is accidental, and that it is not an element of sulphur.

the south coast of the island, and extending inwards as far as the district of Etna. This blue clay formation is considered by Dr. Daubeny of the same age with the gypsum bed of Paris, and therefore more recent than chalk. It contains beds of gypsum and of salt, and the sulphur is in some places associated with splendid crystals of sulphate of strontia. The supply of sulphur derived almost exclusively from Sicily is enormous: the average annual importation into England is between 16 and 17 thousand tons, at from 6*l.* to 10*l.* per ton. It undergoes a rough purification by fusion, and is brought into the market in square or oblong masses or blocks. At Bex, in Switzerland, sulphur occurs in the gypsum of the salt deposit; and it is found in the same rock in many other parts of Europe, generally in beds or masses; in Suabia, and near Schemnitz in Hungary, it is found in veins traversing granite and mica slate; and in the same rocks in Quito in Peru: near Gibraltar, it occurs in fetid limestone. Sulphur is also common in the fissures of lava near volcanic craters: there is a great deposit of this species of sulphur in the plain of the Solfatara near Naples. Sulphur is found abundantly combined with certain metals; the common ores of lead and copper are their *sulphurets*; sulphuret of iron, or *pyrites*, is also a very common mineral.

Sulphur is insoluble in water, and suffers no change by exposure to air. When it is heated to about 180°, it volatilizes, and its peculiar odour is strong and disagreeable; at about 216° it begins to fuse, and between 230° and 270°, it is perfectly liquid, and of a bright brownish-yellow colour; between 300° and 400° it becomes viscid, and of a deep brown colour, but regains its fluidity when cooled; at higher temperatures it again liquifies, and at about 600° it boils, and sublimates in the form of an orange-coloured vapour, and may be collected either in a solid or pulverulent state, according to the rapidity of the process and the size of the condensing vessels. The residue is the *sulphur vivum* of old pharmacy. When sulphur, which has been heated to about 300°, is poured into warm water, it acquires the consistency of soft wax, and hardens on cooling. In this state it is sometimes used to take impressions of gems and medals; it is of a reddish colour, and of the specific gravity 2·3. When slowly cooled after fusion, sulphur forms a fibrous crystalline mass; but Mr. Faraday has remarked that it sometimes retains its fluidity, and does not concrete till touched by some solid body. This state appears somewhat analogous to that of water cooled in a quiescent state below its freezing point. (*Quarterly Journal*, xxi. 392.) The following table shows the results of Dumas's experiments on the influence of temperature upon the colour and properties of sulphur:—

Temperature.		Hot Sulphur.	Sulphur suddenly cooled by immersion in water.
Fahr.	Cent.		
230°	110°	Very liquid: yellow	Very friable: usual colour
284	140	Liquid: deep yellow	Do. do.
338	170	Thick: orange yellow	Friable: do.
374	190	Thicker: orange	{ At first soft and transparent, then friable and opaque: usual colour
428	220	Viscid: reddish	
464 to 500	240 to 260	Very viscid: brown-red	Soft: transparent: amber colour
	Boiling pt.	Less viscid: brown-red	Very soft: transparent: reddish
			Do. do. brown-red.

In order that sulphur may retain its soft or viscid state it is not necessary, as sometimes directed, to keep it long in a fused state, but merely to take care that it has been raised to a due temperature and then suddenly cooled by dropping it into cold water; if poured into the water in mass, the interior cools slowly and reverts to its brittle state: here, therefore, the effect of what may be called *tempering* is the reverse of that produced upon steel, and somewhat corresponds with the phenomena presented by bronze.

Sulphur is commonly met with in three forms; namely, 1. *Massive* or native sulphur, already mentioned. 2. *Stick* or *roll* sulphur, which is chiefly obtained from sulphuret of copper in this country, and elsewhere abundantly from sulphuret of iron, or common pyrites; these ores are roasted, and the fumes received into a long chamber of brick-work, where the sulphur is gradually deposited; it is then purified by fusion, and cast into sticks. In this state, if grasped by the warm hand, it splits with a crackling noise. 3. *Sublimed* sulphur, or *flowers of sulphur*, which is in a pulverulent form, and procured by condensing the vapour of sulphur rapidly in capacious receivers; it is of a peculiar pale yellow colour, and when examined by a microscope appears composed of minute crystals; it is always somewhat sour, and therefore for certain pharmaceutical purposes is directed to be washed with hot water.

The sulphur of commerce occurs in three prevailing colours, namely, lemon yellow verging on green, dark yellow, and brown yellow; these shades result, partly at least, as the above table shows, from the different degrees of heat to which it has been exposed during its fusion or extraction on the great scale, the palest variety having been the least heated. The different modes of purifying sulphur are described by Dr. Ure in the first volume of the *Royal Inst. Journal*. (For a detailed account of the methods of obtaining and purifying sulphur, see also DUMAS: *Chimie appliquée aux Arts*.)

For some pharmaceutical purposes sulphur is precipitated from its alkaline solutions, by an acid, and, when washed and dried, is in the form of a yellowish-gray impalpable powder; this is the *milk of sulphur* and *precipitated sulphur* of the *Pharmacopœia*. Dr. Thomson considers it as a compound of sulphur and water. (*System of Chemistry*, vol. i. p. 285.)

The purity of sulphur may be judged of by heating it gradually upon a piece of platinum leaf; if free from earthy impurities, it should totally evaporate. It should also be perfectly soluble in boiling oil of turpentine. (AIKIN'S *Dictionary*, Art. SULPHUR.) According to Dr. Ure, sulphur is soluble in ten times its weight of boiling oil of turpentine at 316° forming a solution which remains clear at 180° . As it cools to the atmospheric temperature, crystalline needles form, which may be washed with cold alcohol or tepid water. The usual impurities of the sulphur, which are carbonate and sulphate of zinc, oxide and sulphuret of iron, sulphuret of arsenic, and silica, will remain unaffected by the volatile oil, and may be separately eliminated by the curious, though such separation is of little practical importance.

Sulphur dissolves with some difficulty, and in very small proportions, in alcohol; to effect this solution both substances should be brought together in the state of vapour. It is more soluble in sulphuric ether.

It appears from the statements of Dumas and of Mitscherlich that the density of sulphur vapour is about 6.6 (*Ann. de Chim. et Phys.*, L. 170, and LV. 5), so that supposing it to exist in the state of vapour at mean temperature and pressure, 100 cubic inches would weigh 206 grains, and its specific gravity to hydrogen would be as 96 to 1.

When heated in the atmosphere to a little above 300° , sulphur inflames and burns with a peculiar blue light; at a higher temperature its vapour kindles with a purple flame; and in oxygen it burns vividly, with a large lilac-coloured flame.

SULPHUR AND OXYGEN.—There are four definite compounds of sulphur and oxygen, all of which rank among the acids; namely, 1. Sulphurous acid; 2. Sulphuric acid; 3. Hyposulphurous acid; 4. Hyposulphuric acid.

SULPHUROUS ACID. ($S + 2O$), or \hat{S} , or SO_2 , or \ddot{S} . This acid was first examined by Stahl, who called it *phlogisticated sulphuric acid*. Scheele, in 1774, pointed out a method of obtaining it; and about the same time, Priestley procured it in the gaseous form, and ascertained its leading properties. Berthollet examined it in 1782, and 1789 (*Mem. Paris*, 1782, and *Ann. de Chim.*, ii. 54); and in 1797, Fourcroy and Vauquelin published a detailed series of experiments upon it. (*Ann. de Chim.*, xxiv. 229.) Some experiments on it were also published by Dr. Thomson in 1803. (*NICHOLSON'S Journal*, vi. 93.) Its atomic composition was first accurately investigated by Davy, by Gay Lussac, and by Berzelius.

At common temperatures and pressures sulphurous acid is a gaseous body, which may be obtained by several processes. It may be procured directly, by burning sulphur in oxygen gas; or indirectly, by boiling two parts of mercury in three of sulphuric acid; or by heating, in a retort, a mixture of equal parts of black oxide of manganese and sulphur. It must be collected and preserved over mercury; for water takes up rather more than thirty times its bulk of this gas. For all the common purposes of experiment it may be collected in dry stopper-bottles, as directed at page 366. It is often generated by the action of charcoal, wood, and various organic matters upon sulphuric acid, but in those cases it is mixed with carbonic acid. These processes generally resolve themselves into the deoxidizement of sulphuric acid, for when one atom of oxygen is abstracted from that acid, the remaining elements are left in the proportions constituting sulphurous acid.

The specific gravity of sulphurous acid gas is 2.22 (2.2105, TURNER), and 100 cubical inches weigh between 68 and 69 grains. (At 60° and 30 inches Bar., 68.691 grains. TURNER. At 32° , 72.8660 grains. THOMSON.) Its specific gravity compared with hydrogen is as 32 to 1.

Sulphurous acid is one of the most easily condensible of the gases. Monge and Clouet found, that at the freezing point, and under pressure, it assumed a liquid form; the experiments of Faraday place the pressure required for this purpose at two atmospheres. M. Bussy (*Ann. of Phil.*, viii. 307. N. S.) has shown that this acid may be obtained in the liquid form at common atmospheric pressure, by passing it through tubes surrounded by a freezing mixture of salt and snow. (FARADAY'S *Manipula-*

tion, p. 215.) In this state it is a limpid liquid of the sp. gr. of 1.45. It boils at 14° , and evaporates with such rapidity at common temperatures as to generate a great degree of cold; by its aid mercury may easily be frozen, and it produces cold enough to liquify chlorine, ammonia, and cyanogen. It conducts electricity (KEMP). When this liquid sulphurous acid is exposed in a humid state to cold, a crystalline solid is formed, containing about 20 per cent. of water (perhaps 1 equivalent of acid + 1 of water). A similar compound is often observed to invest the bubbles of gas produced by pouring the liquid acid into water.

When sulphur is burned in pure and perfectly dry oxygen, sulphurous acid is produced, without any change in the volume of the gas, so that its composition is learned by the increase of weight; and as 100 cubic inches of oxygen dissolve between 34 and 35 grains of sulphur, it is obvious that sulphurous acid is composed of equal weights of sulphur and oxygen; or of

								Berzelius.
Sulphur	1	..	16	..	50	.. 49.968
Oxygen	2	..	16	..	50	.. 50.032
<hr/>				<hr/>				<hr/>
Sulphurous acid			1		32		100	100.000

According to Mitscherlich's estimate of the specific gravity of sulphur vapour, sulphurous acid consists of 100 volumes of oxygen gas, and 16 of the vapour of sulphur, condensed into 100 volumes: or one volume of oxygen combined with one-sixth of a volume of sulphur vapour constitute one volume of sulphurous acid.

Sulphurous acid gas has a suffocating odour; it is fatal to animal life, and extinguishes most combustibles when immersed into it in an ignited state: hence it is sometimes resorted to for the purpose of extinguishing the burning soot in a chimney, as by throwing a handful of sulphur, in such a case, into the fire: it vividly maintains the combustion of potassium and sodium. At mean temperature and pressure, recently-boiled water takes up about 33 volumes (37, GRAHAM) of sulphurous acid gas; the solution has a sulphurous and somewhat astringent taste, and it bleaches many vegetable colours; but, by keeping, it acquires a sour flavour, and reddens the generality of vegetable blues. Upon some colouring matters, as that of cochineal, it has little action; and when it does destroy colour, the original tint may often be restored by a stronger acid. A red rose, for instance, is bleached by dipping into a solution of sulphurous acid; but the colour is restored by immersion in dilute sulphuric acid. According to Grotthus, the sulphurous acid and certain colouring matters combine into colourless compounds, which are decomposed by more powerful acids. A singular bleaching effect is produced upon some flowers by burning a little sulphur, so that the fumes of the sulphurous acid may come into contact with their petals: the dark-coloured dahlias, and heart's-ease, may thus be amusingly variegated. Obtained by burning sulphur, this acid is much used in bleaching cotton goods (*Quarterly Journ. of Science*, iv. 196), also for whitening silk and wool, and altering the colour of hops.

When the aqueous solution of sulphurous acid is boiled, the gas escapes, but not when it is frozen. Its specific gravity at 60° is 1.05.

Alcohol dissolves sulphurous acid more copiously than water; one volume taking up more than 100 of the gas.

Pure liquid sulphurous acid (that is, the condensed gas,) suffers no decomposition by the voltaic current, but when dissolved in water the solution yields oxygen at the anode, and hydrogen and sulphur at the cathode. A solution containing sulphuric acid in addition, is a better conductor: it gives very little gas at either electrode: that at the anode is oxygen, that at the cathode pure hydrogen, and from the cathode arises a white turbid stream consisting of diffused sulphur. "I conclude that the sulphurous acid was not affected by the electric current, and that the water only was electrically decomposed: that at the anode the oxygen from the water converted the sulphurous into sulphuric acid; and at the cathode, the hydrogen, electrically evolved, decomposed the sulphurous acid, combining with its oxygen, and setting the sulphur free: that the sulphur at the negative electrode was only a secondary result." (FARADAY, *Phil. Trans.*, 1834, p. 97.)

Sulphurous acid suffers no change at a red heat; but if mixed with hydrogen, and passed through a red-hot tube, water is formed and sulphur deposited; under the same circumstances, it is also decomposed by charcoal, by potassium, and sodium, and probably by several other metals. It undergoes no change when mixed with oxygen, unless humidity or water be present, in which case a portion of sulphuric acid is slowly formed. When mixed with chlorine, and in contact with water, sulphurous acid gives rise to sulphuric and hydrochloric acid, but the perfectly dry gases have no mutual action. So also iodine and bromine are without action on sulphurous acid unless water be present, when sulphuric acid, and hydriodic and hydrobromic acids are formed. The chloric, bromic, and iodic acids are decomposed by sulphurous acid, with the evolution of chlorine, bromine, and iodine, and the formation of sulphuric acid. When gaseous sulphurous acid is mixed with hydrochloric, hydriodic, or hydrobromic acid gases, they mutually decompose each other; water, and chloride, iodide and bromide of sulphur, are formed: but when these acids are in aqueous solution they then do not decompose each other. Peroxide of lead, or of manganese, added to the aqueous solution of sulphurous acid, convert it into sulphuric acid, and destroy its odour. With moist nitrous acid vapour, or with liquid nitrous acid, it forms a peculiar crystalline compound which will be referred to under the head *Sulphuric Acid*.

Vapour baths, in which sulphurous acid with or without steam is applied to the surface of the body, have of late years been much resorted to in the treatment of certain cutaneous complaints, and in rheumatic and other painful affections. The arrangements for this purpose employed in Paris are described and depicted by Dumas, (*Chimie App. aux Arts*: see also PEREIRA, *Elements of Materia Medica*.)

SULPHUROUS ACID AND AMMONIA. SULPHITE OF AMMONIA. ($S + 2O$) + $(n + 3h)$, or $\bar{S} + A$.—When sulphurous acid gas is passed into aqueous solution of ammonia, a sulphite of ammonia is formed, which may be obtained in prismatic crystals: exposed to air it absorbs oxygen, and passes into sulphate of ammonia: heated out of contact of air it yields

water, ammonia, and a sublimate of acid sulphite. Sulphite of ammonia is very soluble in water, and produces cold during its solution.

SULFIMIDE.—The mutual action of dry sulphurous acid and ammonia has been studied by Rose: when these gases, deprived of humidity, are combined, they produce deep yellow crystals, which contain the elements of 1 atom of ammonia and 1 atom of sulphurous acid: when there is great excess of sulphurous acid gas present, a compound in which equal volumes are condensed, and which therefore corresponds to a bisulphite of ammonia, is obtained; but no basic compound can be obtained by the employment of any excess of ammonia. The neutral compound has been chiefly examined by Rose; it is termed by Dumas, *Sulfimide*. (*Chim. App. aux Arts*, v. 709.)

Exposed to the air, sulfimide becomes white and deliquesces, and gradually passes into sulphate and hyposulphite of ammonia, and although to some tests it presents the characters of a sulphite of ammonia, with others, and especially with nitrate of silver, it acts as a hyposulphite. Dumas considers it as a hydrated amide, having the formula $(S + O) + (n + 2h) + (h + O)$: these elements are equivalent to those of an anhydrous sulphite of ammonia; or $(n + 3h) + (S + 2O)$.

SULPHURIC ACID. $(S + 3O)$ or S' , or SO_3 or \ddot{S} .—This important acid was formerly chiefly obtained by the distillation of sulphate of iron, or *green vitriol*, and was, therefore, termed *oil of vitriol*. It is now almost exclusively procured in this country by the combustion of a mixture of about eight parts of sulphur and one of nitre. The history of its discovery has already been adverted to (p. 20). The process of its manufacture is generally conducted nearly as follows: the mixture of sulphur and nitre is burned in a furnace, so placed that the resulting fumes may pass into a capacious leaden chamber (frequently 100 feet long, 20 to 30 feet wide, and 10 to 16 feet high), the floor of which is covered with water, and into which steam is also generally introduced: in many works several of these chambers, or *houses*, as they are termed, are ranged side by side in covered buildings. The following cut will serve to give some idea of the internal construction of one of these houses:—*a* is the furnace for the combustion of the sulphur and nitre, the fumes from which pass into the chamber and meet with the steam generated in the boiler *b*; the interior of the chamber is divided into several partitions, *c c*, by the diaphragms *d d*, which are alternately open at top and bottom, so that the vapours pass in the direction of the darts, and are exposed to a large

249

condensing surface. *e* is a chimney or ventilator. The water which collects in the bottom of this chamber gradually becomes more and more

sour, and is, in fact, a diluted sulphuric acid; when it has thus acquired a certain specific gravity it is drawn off into shallow leaden boilers, or evaporators, where it is evaporated till it acquires the specific gravity of 1.70, at which density the acid would begin to act upon the lead, and the heat required for its further evaporation would endanger the softening of the metal; in that degree of concentration, therefore, the acid is run off into boilers, or rather into stills of platinum, which are set upon cast-iron, and in which the further boiling down of the acid is continued until it attains the specific gravity of 1.84; it is then drawn off by a syphon into a platinum cistern or cooler, and is thence transferred into *carbboys*, or large bottles protected by basket-work, each holding about 100 pounds of the acid. Before the introduction of platinum vessels for this purpose, the latter evaporation was performed in glass retorts, the lifting and emptying of which, when containing many pounds of the acid, was a very hazardous operation; the price of the acid fell, in consequence, from fourpence to about three-halfpence, or less, per pound. The manufacture of sulphuric acid is carried on upon a most extensive scale in Great Britain; the quantity annually produced, probably not falling far short of sixty thousand tons, or about one hundred million of pounds, which, at the estimated value of ten shillings per cwt., amounts to above 600,000*l*.

Although the acid obtained by the above process is commonly called *sulphuric acid* (or oil of vitriol) we shall soon find that it is in fact a definite combination of anhydrous sulphuric acid and water, composed of 1 atom anhydrous acid + 1 atom water, and sometimes therefore called a *protosulphate of water*.

In the above process, the theory of which will be presently explained, the sulphurous acid is in fact converted into sulphuric acid by the agency of nitric oxide and water. Several other methods of forming sulphuric acid have been suggested, but not hitherto applied on a large scale; among them the following deserves particular notice:—"When a mixture of sulphurous acid and air is made to pass over spongy platinum at a high temperature, the sulphurous acid is converted into sulphuric acid at the expense of the oxygen of the air. Mr. P. Phillips, who first made this observation, has founded upon it a method of preparing sulphuric acid on the large scale, which although not yet sufficiently tried to establish its advantage as a manufacturing process, is still of great interest in a scientific point of view, and deserves consideration. Sulphur is burned, or iron pyrites in place of it, and the sulphurous acid produced is mixed with an excess of air by a blowing apparatus, and carried through a tube filled with the platinum sponge, or balls of fine platinum wire. The vapours of sulphuric acid formed which are mixed with the nitrogen of the air are condensed in a long and narrow vessel of lead in an upright position, filled with pebbles which are kept constantly wet by a small stream of water admitted at the top, and which percolates downwards." (GRAHAM.)

It has long been an object with the manufacturer to obtain sulphuric acid without the aid of nitre, and a patent has been obtained for a process of this kind by Mr. Hill. It consists in submitting coarsely-powdered iron-pyrites (bisulphuret of iron) to a red heat, in cylinders communi-

eating with a leaden chamber containing water; part of the sulphur, as it burns out of the pyrites, appears at once to pass into the state of sulphuric acid; with the help of nitre the pyrites might perhaps be more economically employed.

The great consumers of sulphuric acid are the manufacturers of soda from common salt, and of chlorine or chloride of lime for the use of bleachers; there are also many chemical products dependent upon it, such as citric, tartaric, nitric, and hydrochloric acids; sulphate of soda; and sulphate of magnesia; and others of less note; it is also in constant demand by dyers, calico-printers, bleachers of various materials, the manufacturers of blacking, of soda-water, of various pigments, and by the refiners of gold and silver, and the purifiers of oil and tallow.

Sulphuric acid, as it usually occurs, is a limpid, inodorous, colourless fluid, of an oily consistence, and of the specific gravity of about 1·84. Dr. Ure observes that he has frequently boiled the pure acid till only one-half remained in the retort; yet at the temperature of 60° Fahrenheit, has never found the specific gravity of acid, so concentrated, to exceed 1·8455. The number 1·850, which has been assigned for the density of pure oil of vitriol, is erroneous, and ought to be corrected. Genuine commercial acid should never surpass 1·8455; when it is denser, we may infer sophistication, or negligence, in the manufacture.

Sulphuric acid boils at a temperature of about 620°, which, therefore, approaches a red heat, and distils over without decomposition. The density of its vapour was found by Mitscherlich to be 3. The calculated density is 2·762. Its boiling-point diminishes with its dilution; when of the specific gravity of 1·78 it boils at 435°; and at 350°, when its specific gravity is 1·65. (DALTON, *Chem. Phil.*, ii. 404.) In illustration of its fixedness at all common temperatures, Bellani placed a piece of zinc foil in the upper part of a closed bottle, the bottom of which was covered with the concentrated acid: the metal retained its bright surface at the end of two years. The concentrated acid freezes at -15°; and at the same time contracts considerably in its dimensions: acid of the specific gravity of 1·78 (which is a definite hydrate) containing 1 atom of anhydrous sulphuric acid and 2 atoms of water, on the contrary, freezes at +40°, but if the density be either increased or diminished, a greater cold is required for its congelation. (MACNAB, *Phil. Trans.*, vol. LXXvii., and KEIR, *Phil. Trans.*, vol. LXXviii.)

Sulphuric acid is intensely acid and caustic; it acts speedily upon the cuticle, occasioning a biting sensation, and a soapy feel of the part: its taste, even when very largely diluted, is extremely sour, and it powerfully reddens litmus. It has a strong attraction for water, so that when exposed for a short time to air, it absorbs aqueous vapour from the atmosphere and increases rapidly in bulk; in moist weather three parts increase to four in the course of 24 hours, and by longer exposure, a much larger quantity of water is taken up, so that the acid requires to be preserved in well-stopped vessels. It is this property which renders it applicable to the drying of certain gases, and to the purposes of evaporation and desiccation under the exhausted receiver of the air-pump; and hence the cold produced in the experiment described at p. 184. When sulphuric acid is suddenly mixed with water, mutual condensation ensues, much

heat, therefore, is evolved (p. 164). Four parts of acid and one of water produce, when thus mixed, a temperature $= 300^{\circ}$. According to Dr. Ure, the greatest heat is evolved by mixing 73 of acid with 27 of water. Even a boiling temperature does not prevent sulphuric acid taking up moisture from the air: hence it cannot be concentrated so well in an open as in a close vessel; on which account retorts of glass, or platinum-stills are used for the last stage of its concentration by the manufacturers. The mixture of sulphuric acid with ice or snow causes its immediate liquifaction, and as this liquifaction, consistently with the theory of latent heat, produces cold, while on the other hand the union of the acid with the water evolves heat, the resulting temperature of such mixture, depends upon the relative proportions of the substances mixed. Four parts of acid and one of snow, or pounded ice, evolve heat; but four parts of snow and one of acid generate cold.

Sulphuric acid possesses intense chemical powers; it displaces the greater number of other acids from their combinations; and, probably in consequence of its strong affinity for water, it chars most animal and vegetable substances, and acquires a brown tinge from the smallest particles of straw, cement, or even dust, that accidentally fall into it: it appears capable of dissolving small portions of charcoal, and also of sulphur, tellurium, and selenium; these substances give it various tints of brown, red, and green, or blue, and are precipitated when the acid is diluted with water; but if heat be applied they are oxidized at the expense of the acid, and sulphurous acid is evolved.

When heated with charcoal, sulphuric acid gives rise to the production of carbonic and sulphurous acids; with phosphorus it produces phosphoric and sulphurous acids; and, with sulphur, sulphurous acid is the only product. It is decomposed by several of the metals, which become oxidized, and evolve sulphurous acid, as shown in the production of this acid, by boiling sulphuric acid with mercury, tin, lead, &c. When metals are dissolved in *diluted* sulphuric acid, the water only is decomposed, and its oxygen, being transferred to the metal, forms a *metallic oxide*, which unites to the sulphuric acid to form a *sulphate*, whilst the hydrogen is evolved in the gaseous form.

It appears from Mr. Faraday's experiments (*Phil. Trans.*, 1834, p. 82), that sulphuric acid is not electrolysable, and that the anhydrous acid is not a conductor. The appearance of sulphur, when the common acid is subjected to the action of a powerful battery, at the negative pole, is referable to a secondary action (p. 314). But the electrolysis of hydrated sulphuric acid, and more especially of some of the sulphates, involves many interesting points respecting the ultimate constitution of those bodies, which we shall again refer to when considering the *salts of the metals*. (DANIELL, *Phil. Trans.*, 1839, p. 89; 1840, p. 209.)

The presence of sulphuric acid, either free or in any soluble combination, is detected by solution of baryta: if, for instance, a solution of chloride of barium be added to any liquid containing sulphuric acid or a sulphate, a white precipitate falls, which is *sulphate of baryta*, and is characterized by its insolubility in acids and alkalis. 117 parts of dry sulphate of baryta are equivalent to 40 of dry sulphuric acid. The

soluble salts of lead are also delicate tests of the presence of sulphuric acid: they indicate it by a white precipitate, insoluble in nitric acid.

In consequence of the great consumption of sulphuric acid, it is highly important to the consumer to be able to judge of its value and purity: the *specific gravity* may generally be depended upon as indicative of its strength, and we have several valuable tables showing the quantity of real or dry sulphuric acid contained in the liquid or diluted acid of various specific gravities.

Mr. Dalton (*New System of Chemical Philosophy*, vol. ii. p. 404) has published a table, exhibiting the specific gravity and boiling-point of the acid, of various strengths. Dr. Ure has also given several tables relating to this subject, in his *Experiments to determine the Law of Progression followed in the Density of Sulphuric Acid at different Degrees of Dilution*. (*Quarterly Journal of Science and the Arts*, vol. iv. p. 114.) See, also, URE'S *Dictionary*, Art. ACID (SULPHURIC). An extremely useful table of this kind will also be found in PARKES' *Essays* (vol. ii. p. 444).

The following is Dr. Ure's table:—

Liq.	Sp. Gr.	Dry.	Liq.	Sp. Gr.	Dry.	Liq.	Sp. Gr.	Dry.

In ascertaining the specific gravity of sulphuric acid, the *temperature* requires minute attention, because from the small specific heat of the acid it is easily affected, and because it greatly influences the density. On removing the thermometer from the acid, it speedily rises in the air to 75° or 80° , though the temperature of the apartment be only 60° ; afterwards it slowly falls to 60° . If this thermometer, having its bulb covered with a film of dilute acid (from absorbing atmospheric moisture), be plunged into a strong acid, it will rise 10° or more, and an elevation equal to 10° diminishes the density of oil of vitriol by 0.005; 1000 parts being heated from 60° to 212° , become 1043 in volume, and the sp. gr. which was 1.848, falls to 1.772, being the number corresponding to a dilution of 14 per cent. of water.

But it is also necessary to ascertain that the sulphuric acid under examination leaves no residue on evaporation. If the acid of commerce contain dissolved sulphate of lead, it becomes turbid on dilution, so that its remaining clear when mixed with water is some proof of its purity, as far at least as lead is concerned. The simplest mode of judging of the purity of this acid is to introduce a given weight into a platinum capsule and evaporate it; if it leaves more than one *per cent.* of solid residue, it has probably been intentionally sophisticated. It often holds sulphate of potassa in solution, 2.5 per cent. of which increases the specific gravity of the concentrated acid to 1.860; hence the necessity, where accuracy is required, of determining the value of the acid by its *saturating power*. For this purpose, a given weight of the acid is diluted with six or eight parts of water, and pure anhydrous carbonate of soda added until the solution is exactly neutral (see *Alcalimetry*). Every 54 parts of such carbonate of soda required for this purpose, are equivalent to 40 parts of the anhydrous acid, or to 49 of the liquid sulphuric acid, or oil of vitriol, of the specific gravity of 1.84.

For some purposes of delicate chemical research, it is necessary to purify the acid by distillation, and this operation requires much precaution, when conducted in a glass retort, in consequence of the violent jerks which the production of its vapour occasions, and which often break the vessel; this may be prevented by putting some strips of platinum into the acid; it then boils quietly, and it is only necessary to take care that the neck of the retort and receiver are not broken in consequence of the high temperature of the condensing acid. This very useful contrivance to the practical chemist was shown me many years ago by Sir James South.

Dr. Ure has the following remarks on the distillation of this acid:—
 “I take a plain glass retort, capable of holding from two to four quarts of water, and put into it about a pint measure of the sulphuric acid, (and a few fragments of glass,) connecting the retort with a large globular receiver, by means of a glass tube four feet long, and from one to two inches in diameter. The tube fits very loosely at both ends. The retort is placed over a charcoal fire, and the flame is made to play gently on its bottom. When the acid begins to boil smartly, sudden explosions of dense vapour rush forth from time to time, which would infallibly break small vessels. Here, however, these expansions are safely permitted, by the large capacity of the retort and receiver, as well as by

the easy communication with the air at both ends of the adopter tube. Should the retort, indeed, be exposed to a great intensity of flame, the vapour will no doubt be generated with incoercible rapidity, and break the apparatus. But this accident can proceed only from gross imprudence. It resembles, in suddenness, the explosion of gunpowder, and illustrates admirably Dr. Black's observation, that, but for the great latent heat of steam, a mass of water, powerfully heated, would explode on reaching the boiling temperature. I have ascertained, that the specific caloric of the vapour of sulphuric acid is very small, and hence the danger to which rash operators may be exposed during its distillation. Hence, also, it is unnecessary to surround the receiver with cold water, as when alcohol and most other liquids are distilled. Indeed the application of cold to the bottom of the receiver generally causes it, in the present operation, to crack. By the above method, I have made the concentrated oil of vitriol flow over in a continuous slender stream, without the globe becoming sensibly hot."

Cases of poisoning by sulphuric acid are not unfrequent; the best antidotes are copious draughts of chalk and water, and of carbonate of magnesia and water. (ORFILA.)

NATIVE SULPHURIC ACID has been found by Professor Baldassari, in the cavities of a small volcanic hill, called Zoccolino, near Sienna.

ANHYDROUS SULPHURIC ACID.—When sulphuric acid was procured by the distillation of green vitriol, it was frequently observed that a portion concreted into a white mass of radiated crystals. The same substance has also been remarked as occasionally formed in the acid of the English manufacturers. It has been called *glacial* or *fuming sulphuric acid*, and is considered as the pure, or *anhydrous acid*. When crystallized green vitriol, or protosulphate of iron, is exposed to a dull red heat, it crumbles down into a white powder, and loses the greater part of its water of crystallization. (See *Sulphate of Iron*.) In this state it is put into a coated earthen or green glass retort, and gradually exposed to an intense red or even white heat; a dark-coloured acid liquor distils over, of a specific gravity of about 1.89, which has been called *Nordhausen*, or *German sulphuric acid*, which smokes when exposed to air, from the escape of the highly volatile *dry* sulphuric acid, which is united in the brown liquid with a portion of hydrated acid. This brown, fuming acid, is in request as a ready and perfect solvent of indigo. When it is kept at a temperature below 32°, crystals form in it, which according to Mitscherlich are a definite compound of 2 atoms of anhydrous acid and 1 atom of water; it is resolved by heat into the common and the anhydrous acid.

The dry or *anhydrous sulphuric acid* may be separated from the brown or Nordhausen acid, by careful distillation from a retort into a dry and cold receiver; it passes over in drops, which concrete, on cooling, into a tenacious crystalline mass. This acid is liquid at a temperature above 66°; and at 78° its specific gravity, according to Bussy, is 1.97. (*Journal de Pharmacie*, x. 368.) When it has once congealed it is difficult to fuse it, because the first portions heated become vapour, and propel the rest forward; by slight pressure, however, this may be prevented. When kept in a temperature between 75° and 80° it gradually liquifies. At a

temperature somewhat above this, which, however, has not been accurately determined, it passes into the state of colourless vapour. In the absence of all moisture, it has no action upon litmus paper. It dissolves sulphur, forming brown, green, or blue compounds, according to the quantity taken up; when water is added, the sulphur is deposited. It also dissolves iodine, forming with it a blue-green solution. Passed through a red-hot porcelain tube, anhydrous sulphuric acid is resolved into *one volume of oxygen and two of sulphurous acid*. Caustic lime or baryta heated in its vapour, become ignited, and converted into sulphates. The attraction of this anhydrous acid for water is such as to produce intense heat, and a hissing noise, when small portions of it are thrown into that fluid; and if a sufficient quantity of it be added to such a proportion of water as is required to convert it into hydrated acid, they combine with heat, light, and explosion.

The liquid acid, from sulphate of iron, yields about one-fourth its weight of anhydrous acid by distillation; but if this cannot be procured, the anhydrous acid may be obtained, according to Berzelius, by the distillation of such other sulphates as easily part with their acid: those sulphates which require a very elevated temperature, are less fit for the purpose, because the acid is then apt to be resolved into sulphurous acid and oxygen. Bisulphate of soda, or persulphate of iron, may thus be employed. The former may be made by mixing in a crucible three parts of thoroughly-desiccated sulphate of soda with two of common sulphuric acid, and heating them till the ebullition occasioned by the escape of water has ceased. The resulting mass is then to be pulverized, transferred to a porcelain retort, and distilled at a red heat; the acid which passes over may be collected in a receiver cooled by ice: it is generally of a dark colour, which appears to arise from dust accidentally present. A persulphate of iron, applicable to the same purpose, may be procured by mixing finely-powdered peroxide of iron into a thin paste with common sulphuric acid, and gradually heating it (below redness) till they combine into a saline mass, which is to be powdered and subjected to distillation as before. The acid thus obtained generally contains a little water, and if it crystallizes, it forms brittle foliaceous crystals. Carefully distilled by a gentle heat, the anhydrous acid passes over, and common liquid acid (hydrated) remains in the retort.

It appears, then, that this extraordinary substance, which is thus volatile and easy of congelation, forms, by combining with water, the fixed and difficultly-congealable liquid which we commonly term *sulphuric acid*, or *oil of vitriol*, and that it contains sulphur and oxygen in the same proportions as they exist in the dry sulphates. From its resolution when passed through a red-hot tube, into one volume of sulphurous acid and half a volume of oxygen, and likewise from the experiments of Berzelius upon the direct acidification of sulphur, it appears that *anhydrous sulphuric acid* consists of

					Berzelius.			
Sulphur	.	.	1	.	16	.	40	40.14
Oxygen	.	.	3	.	24	.	60	59.86
<hr/>				<hr/>				
Anhydrous Sulphuric Acid	1				40		100	100.00

And the liquid, hydrous, or common sulphuric acid consists of

				Davy and Dalton.
Dry sulphuric acid	1	40	81.63	81
Water	1	9	18.37	19
Hydrate of Sulphuric Acid	1	49	100.00	100

The compound of sulphuric acid and water of the specific gravity 1.78, which has been above alluded to as congealing at 40° remains solid till raised to 45° , and is a definite combination of 1 atom of anhydrous acid + 2 atoms of water; and lastly, the acid of specific gravity 1.632 appears also to be a definite hydrate containing 1 atom of anhydrous acid and 3 atoms of water, for it is to this strength that a dilute sulphuric acid evaporated in vacuo at 212° is reduced, and it is also in these proportions that sulphuric acid and water suffer the greatest diminution of bulk in combining. It would appear, therefore, that there are four definite hydrates of sulphuric acid; of which the following are the formulæ, and their abbreviations:—

	Formulæ.	Abbreviations
Anhydrous Acid	$(S + 3O)$	S'
Hydrate in the Nordhausen Acid	$2(S + 3O) + (h + o)$	$2S' + q$
Oil of Vitriol, sp. gr. 1.845	$(S + 3O) + (h + o)$	$S' + q$
Acid of sp. gr. 1.780	$(S + 3O) + 2(h + o)$	$S' + 2q$
Acid of sp. gr. 1.632	$(S + 3O) + 3(h + o)$	$S' + 3q$

Mr. Graham, in reference to the composition of the *sulphates*, arranges these formulæ as follows:—

Hydrate in the Nordhausen Acid	$(q + 2S')$	or	$HO, 2SO_3$
Oil of Vitriol	$(q + S')$		HO, SO_3
Acid of sp. gr. 1.780	$(q + S') + q'$		$HO, SO_3 + HO.$
Acid of sp. gr. 1.632	$(q + S') + 2q$		$HO, SO_3 + 2HO.$

THEORY OF THE PRODUCTION OF SULPHURIC ACID.—Having stated the properties and composition of anhydrous, and common sulphuric acid, we may now revert to the *theory of its formation* in the process of the combustion of sulphur and nitre. It was first supposed that the nitre merely yielded oxygen directly to the sulphur and so effected its perfect acidification; but the small quantity of nitre required, and the production of sulphurous and not sulphuric acid, when sulphur is either burned alone in pure oxygen gas, or when it is heated with peroxide of manganese and other substances which readily impart oxygen, seemed to indicate some other power possessed by the nitre; that this is the case was proved by Clément and Désormes (*Ann. de Chim.*, lix.), and by Davy (*Elements of Chem. Philos.*, 276), to whom we owe the following explanation of the phenomena.

The sulphur by burning in contact with atmospheric air forms *sulphurous acid*; the nitre is at the same time decomposed, and yields *nitrous acid*. When these vapours (*i. e.*, sulphurous and nitrous acids) are perfectly dry, they do not act upon each other, but moisture being present in small quantity, they form a white solid, which is instantly decomposed by the contact of water; the nitrous acid reverts to the state of nitric oxide,

having transferred one additional proportional of oxygen to the sulphurous acid, and, with water, producing the sulphuric acid; while the nitric oxide, by the action of the air, again affords nitrous acid, which plays the same part as before.

Sulphurous acid consists of

16	Oxygen. 8	}	$16+16=32$
	8		

And nitrous acid contains

14	Oxygen. 8	}	$32+14=46$
	8		
	8		
	8		

Hence every *two* proportionals of sulphurous acid require *one* of nitrous acid, which transfers *two* of oxygen, and passes back into the state of nitric oxide, sulphuric acid being, at the same time, produced.

The gases, therefore, before decomposition, may be thus represented:—

Sulphur.	
16	Oxygen. 8
	8
Sulphur.	8
16	8
	8
Two proportionals of Sulphurous Acid.	

Nitrogen.	Oxygen. 8
14	8
	8
	8
One proportional of Nitrous Acid.	

And after decomposition as follows:—

Sulphur.					
16	Oxygen. 8	}	24		
	8				
Sulphur.	8	}	24		
	8				
16	Oxygen. 8	}	24		
	8				
	8				
Two proportionals of Sulphuric Acid.					
Nitrogen.					
14	Oxygen. 8	}	16		
	8				
One proportional of Nitric Oxide.					

Or the changes may be thus represented more briefly in symbols; namely two proportionals of *sulphurous acid*, and one of *nitrous acid*, $2(S + 2O)$

$+(n + 4O)$, become two proportionals of *sulphuric acid*, and one of *nitric oxide*, $2(S + 3O) + (n + 2O)$.

When liquid hyponitrous acid is mixed with sulphuric acid, a crystallized compound of the two acids is formed, provided the temperature be not too high, which, when put into water, evolves nitric oxide gas, and is, according to Gay Lussac, analogous to the above-mentioned substance produced by mixing humid sulphurous and nitrous acid gases. (*Ann. de Chim. et Phys.*, i. 408.)

SULPHURIC ACID AND AMMONIA. SULPHATE OF AMMONIA. GLAUBER'S SECRET SAL-AMMONIAC. SULPHATE OF OXIDE OF AMMONIUM.—This salt may be obtained directly by pouring a few drops of sulphuric acid into a bottle of gaseous ammonia; the ammonia is rapidly absorbed, and the salt crystallizes on the sides of the jar. It is usually prepared by saturating dilute sulphuric acid with *carbonate of ammonia*, or by decomposing hydrochlorate of ammonia by sulphuric acid. It is important as a source of *hydrochlorate of ammonia*, which is obtained by sublimation from a mixture of chloride of sodium and sulphate of ammonia; by this process sulphate of soda is also formed. (See *Sodium*.) For these purposes the *ammoniacal liquor* of gas-works, produced during the destructive distillation of coal, and the impure carbonates of ammonia formed by the distillation of bones and other refuse animal matters, are saturated by sulphuric acid, and the resulting sulphate of ammonia purified by crystallization.

Sulphate of ammonia, in its driest state, includes one proportional of water. In its common form of six-sided prismatic crystals, it contains, according to Berzelius, two proportionals of water, being composed of

				Berzelius.
Ammonia	1	17	22.7	22.6
Sulphuric acid	1	40	53.3	53.1
Water	2	18	24.0	24.3
<hr/>				
Crystallized sulphate } of ammonia . . . }	1	75	100.0	100.0

It is soluble in two parts of water at 60° and in one at 212° . Its taste is bitter and pungent. When heated, it melts and in part sublimes, ammonia is given off, and a *bi-sulphate* remains containing 2 proportionals of acid + 1 of ammonia: at a higher temperature, nitrogen and water are given out, and sulphite of ammonia (or probably sulfimide) is formed.

To assimilate the composition of this salt with the other sulphates, it is assumed to be a *sulphate of oxide of ammonium*; it cannot exist without the atom of water belonging to the sulphuric acid, and is not formed, as we shall presently find, by the mutual action of ammonia and anhydrous sulphuric acid: upon this (hypothetical) view therefore of its constitution, ammonia becomes converted into ammonium by uniting to the hydrogen of the water in the acid, and the oxygen of this water converts the ammonium ($n + 4h$) into oxide of ammonium ($n + 4h$) + O , and this, combined with the anhydrous sulphuric acid forms a sulphate of oxide of ammonium: it is evident that the elements of this hypothetical anhydrous sulphate of oxide of ammonium are equivalent to those of the hydrated sulphate of ammonia; for

Sulphate of Oxide of Ammonium.

=

Hydrated Sulphate of Ammonia.

ANHYDROUS SULPHURIC ACID AND AMMONIA. SULFAMIDE. —The principal evidence in favour of the above view of the constitution of the sulphate of ammonia is derived from *the action of anhydrous sulphuric acid on ammonia*. By conducting dry gaseous ammonia into a glass vessel coated with a thin film of anhydrous sulphuric acid, Rose obtained a crystallized compound, differing in form from sulphate of ammonia, and in which neither sulphuric acid nor ammonia are evident to the usual tests, although their elements must manifestly be included in the compound: it seems probable, therefore, that it may be an *amide* (a hydrated sulfamide) for the elements

Anhydrous Sulphate of Ammonia.

=

Sulfamide and Water.

But the electrolytic decomposition of a solution of sulphate of ammonia, the phenomena of which have been described by Daniell (*Phil. Trans.*, 1839, p. 111), furnishes another view of the constitution of this and other sulphates, which on many accounts is extremely interesting and important in its theoretical bearings. Mr. Daniell found that hydrated sulphate of ammonia $= (n+3h)+(s+3o)+(h+o)$ is resolved by electrolysis into 1 equivalent of sulphur and 4 of oxygen, given off at the anelectrode, and into 1 equivalent of nitrogen and 4 equivalents of hydrogen, given off at the cathelectrode; so that its electrolytic formula would be $(n+4h)+(s+4o)$; thus representing it, not as a sulphate of oxide of ammonium, but as a compound of ammonium $(n+4h)$ with a peculiar anion composed of 1 equivalent of sulphur and 4 of oxygen $(s+4o)$. Such an anion Mr. Daniell provisionally designates *oxysulphion*; and hence, the common sulphate of ammonia he terms *oxysulphion of ammonium*.

NATIVE SULPHATE OF AMMONIA is sometimes found in volcanic products; it occurs in stalactitic concretions of a whitish or yellowish colour, and covered with a white efflorescence: it has thus been procured from fissures in the earth surrounding certain small lakes in Tuscany, near Sienna; and among the products of Etna and Vesuvius; it has been termed by Karsten, *Mascagnine*, from the name of its discoverer.

HYPOSULPHUROUS ACID. $(2s+2o)$ or $\underline{s'}$ or SO_2+s . —The existence of an acid compound of sulphur and oxygen, containing *one* atom of sulphur and *one* of oxygen ($16+8=24$), was first inferred by Dr. Thomson, in 1817, and the salts containing such a combination were originally described by Gay Lussac (*Ann. de Chim.*, lxxxv.), under the name of *sulphuretted sulphites*. Higgins (*Comparative View*, p. 49) and Berthollet had previously found that iron and zinc might be dissolved in aqueous sulphurous acid, without any evolution of hydrogen gas, and that they formed peculiar colourless crystallizable salts, which, acted upon by certain other acids, evolved sulphurous acid and sulphur. By exposing sulphuret of sodium in solution to the air, Vauquelin obtained an analogous compound of soda. Thomson first suggested the existence of a peculiar acid composed of sulphur with a minimum of oxygen, in these

compounds, in 1817 (*Syst. of Chem.*), and they were afterwards examined with much precision and ability by Herschel. (*Edin. Phil. Jour.*, i.) This acid has not been examined in a separate state, though Berzelius has suggested the probability of its existence in some of those peculiar coloured compounds of anhydrous sulphuric acid and sulphur, which have been above adverted to. When we attempt to decompose its compounds in the humid way, sulphurous acid escapes, and sulphur is precipitated. By adding slight excess of sulphuric acid to a dilute solution of hyposulphite of strontia, Sir John Herschel succeeded in separating the acid, but it very soon began to undergo spontaneous decomposition, and was immediately resolved into sulphurous acid and sulphur by heat.

Hyposulphurous acid is formed when *sulphites* are digested in close vessels with sulphur; or when solutions of the sulphurets of the alkaline bases are exposed to the air till they become colourless: it is also produced by the action of zinc or iron-filings upon the solution of sulphurous acid in water, and from these salts it may be transferred to several other bases. In the first case, the oxygen of the sulphurous acid divides itself between the original and the newly-added sulphur. In the latter, the zinc or iron combines with half the oxygen of the sulphurous acid; and the other half, remaining in combination with the sulphur, forms the new acid.

It has been shown by Rose (POGGENDORFF's *Annalen*, xxi.), that although the ratio of the sulphur to the oxygen, in this acid, is as 16 to 8, its *equivalent*, or combining proportion, is not 24, but 48, hence it must be considered as a compound of

Sulphur	.	.	.	2	.	32	.	66.67	} = {	Sulphur	.	.	.	1	.	16	.	33.33

<hr/>										<hr/>								
Hyposulphurous acid				1		48		100.00						1		48		100.00

The *hyposulphites* are mostly soluble and of a bitter taste: the solutions of the alkaline hyposulphites occasion black precipitates in the nitrates of silver and mercury, which are *sulphurets*: the hyposulphites of lead and of baryta are thrown down in the form of white insoluble powders: the neutral hyposulphites dissolve recently-precipitated chloride of silver, and form with it a compound of a very sweet taste.

HYPOSULPHURIC ACID ($2S + 5O$) or S' or S_2O_5 , was discovered in 1819 by Gay Lussac and Welther. It was accidentally formed in an attempt to analyze oxide of manganese by the employment of sulphurous acid, when a peculiar salt was formed, which did not precipitate baryta. This salt was afterwards found to contain a distinct acid of sulphur, to which Gay Lussac gave the above name. (*Ann. de Chim. et Phys.*, x.) It is obtained by passing a current of sulphurous acid through a cold mixture of finely-powdered and pure peroxide of manganese and water. A solution is obtained, which is filtered and thoroughly agitated and digested with hydrated baryta, which must be added in small excess. The sulphuric acid and the greater part of the oxide of manganese are thus precipitated. The solution is again filtered and evaporated till it crystallizes, and the crystals of *hyposulphate of baryta* are a second time dissolved and obtained by evaporation, in order to procure them free from

manganese; they are then dried, powdered, weighed, and dissolved in water; and to every hundred parts of the dissolved salt, 18·78 parts of sulphuric acid, of the specific gravity of 1·84, diluted with four parts of water, are added. The baryta is thus thrown down in the state of sulphate, and the new acid remains in solution. Having been filtered, it is to be concentrated by exposure under the exhausted receiver of the air-pump, including a vessel of sulphuric acid, till it acquires the density of 1·347. If its exposure and evaporation be continued beyond this point, it is resolved into sulphuric and sulphurous acids. A temperature of 212° effects the same change in its composition. It is inodorous, sour, and reddens vegetable blues. It has not been obtained in an anhydrous state.

Neither oxygen, nor chlorine, nor nitric acid, nor peroxide of manganese, affect the composition of hyposulphuric acid at common temperatures; it dissolves zinc with the evolution of hydrogen, and hyposulphate of zinc results. It saturates the salifiable bases; and with lime, baryta, strontia, and protoxide of lead, it forms *soluble* compounds; whereas those formed by these bases with the sulphuric acid, are difficultly soluble or insoluble. Its salts, however, are not permanent at high temperatures, but when heated they are resolved into sulphates, with the escape of sulphurous acid; notwithstanding this, they remain *neutral*, though the quantity of sulphurous acid which escapes is such as would itself have saturated the base. The elements of this acid are in the relative proportions of 1 atom of sulphur and 2·5 oxygen, but its equivalent is not 36, but 72, hence it is constituted of

SULPHUR AND CHLORINE. CHLORIDE OF SULPHUR. (*S + C*) or *S Cl*.—This compound was first described by Dr. Thomson, in 1804 (*NICHOLSON'S Journal*, vol. viii.); and afterwards more fully examined by Berthollet, junior. (*Mém. d'Arcueil*, t. i.) The chlorides of sulphur have also been examined by Rose (*POGGEND. Ann.*, xxi., 431), and by Dumas (*Ann. de Chim. et Phys.*, xlix. 205). When sulphur is heated in excess of dry chlorine, it absorbs rather more than twice its weight of that gas. Ten grains of sulphur absorb 30 cubic inches of chlorine, and produce a liquid of a greenish-yellow, by transmitted light, but orange-red by reflected light. (*DAVY, Elements*, p. 280.) The combination also takes place at common temperatures, and may be effected by passing excess of chlorine through a tube containing powdered sulphur. Chloride of sulphur exhales suffocating and irritating fumes when exposed to the air. Its specific gravity is 1·6: it is volatile below 200°. It boils at 280°, yielding vapour of the density of 4·70. It does not affect dry vegetable blues; but when water is present, it instantly reddens them, sulphur is deposited, and sulphurous, sulphuric, and hydrochloric acids are formed, in consequence of a decomposition of the water. It dissolves sulphur and phosphorus, and decomposes ammonia, according to Grouvelle, but according to Thomson it combines with ammonia, forming a purple or yellow compound. It also decomposes alcohol and ether: it is decomposed by

mercury, heat being evolved, sulphur deposited, and chloride of mercury formed. A fragment of potassium dropped into it presently burns and explodes. It absorbs phosgene gas. According to Davy, although this compound readily dissolves sulphur, it is incapable of absorbing chlorine. From the analysis of Davy and Dumas it consists of

DICHLORIDE OF SULPHUR. BISULPHURET OF CHLORINE. SUBCHLORIDE OF SULPHUR ($2S + Cl$) or S_2Cl .—When the preceding liquid is saturated with sulphur, it deposits a portion, often in crystals, but retains, according to Bucholz, one additional proportional of sulphur, forming a yellow-brown liquid of the specific gravity of 1.700 and possessed of the general properties of the preceding. I have obtained beautiful tetraëdral crystals of sulphur from this liquid, and their deposition is remarkably influenced by light; it appears gradually to deposit the whole of its excess of sulphur. According to Rose (POGGENDORFF, *Ann.*, xxi.) this is the only chloride of sulphur, and the preceding compound analyzed by Davy and Dumas is a solution of chlorine in the dichloride. It consists of

Sulphur	. .	2	. .	32	. .	Rose.

SULPHUR AND IODINE. IODIDE OF SULPHUR. ($S + i$).—Sulphur and iodine readily unite by a gentle heat, and form a black crystallizable compound, first described by Gay Lussac. (*Ann. de Chim.*, xci.) It is decomposed by a degree of heat a little exceeding that required for its formation, and, when boiled in water, the iodine goes off with the steam, and sulphur remains. It is probably a compound of one proportional of each of its components.

SULPHUR AND BROMINE. BROMIDE OF SULPHUR. ($S + b$).—When bromine is digested with sulphur, a red liquid compound results, which emits fumes when exposed to air, and has little action upon dry litmus paper, but powerfully reddens it when moist. It dissolves both bromine and sulphur. It is slowly acted on by cold water, but at 212° the action is violent, sulphuretted hydrogen is evolved, and hydrobromic and sulphuric acids are formed. Chlorine decomposes the bromide of sulphur, and chloride of sulphur is formed, with the evolution of bromine. The composition of this bromide has not been determined.

SULPHUR AND FLUORINE.—Davy obtained a fuming liquid, *Fluoride of Sulphur*, by distilling a mixture of sulphur and fluoride of lead.

SULPHUR AND HYDROGEN. SULPHURETTED HYDROGEN GAS. HYDROTHIONIC ACID. HYDROSULPHURIC ACID. SULPHYDRIC ACID. ($h + s$) or hs' , or HS .—This compound of sulphur and hydrogen was discovered by Scheele in 1777. When sulphur is heated or sublimed in hydrogen gas,

or when the gas is passed through melted sulphur, a small portion of sulphuretted hydrogen is slowly formed, but the action is very imperfect. The gas is readily obtained when sulphur is presented to *nascent* hydrogen, which is the case when proto-sulphuret of iron is acted upon by dilute sulphuric acid, or when one part of bruised sulphuret of antimony is heated with four of hydrochloric acid; or one part of pulverized sulphur and two of iron-filings may be made into a thin paste with water, and heated in a flask till the mixture blackens, after which, the addition of sulphuric acid diluted with four times its bulk of water, causes an abundant evolution of sulphuretted hydrogen. (*Ann. de Chim. et Phys.*, vii. 314.) In the case of the evolution of sulphuretted hydrogen by the action of sulphuric acid and water upon the proto-sulphuret of iron, water is decomposed, its hydrogen combines with the sulphur of the sulphuret to form sulphuretted hydrogen, and its oxygen converts the iron into protoxide, which, combining with the sulphuric acid, forms proto-sulphate of iron. When sesqui-sulphuret of antimony and hydrochloric acid are employed, sesqui-chloride of antimony is formed, and the hydrogen of the acid unites to the sulphur of the sulphuret to form sulphuretted hydrogen. These reactions are expressed in the following equations :

Dumas recommends sulphuret of calcium, or the double sulphuret of sodium, and iron obtained by fusing powdered pyrites with half its weight of dry carbonate of soda at a red heat, as sources of sulphuretted hydrogen when its rapid evolution is required; these sulphurets are to be acted on by hydrochloric acid.

Sulphuretted hydrogen is gaseous at common temperatures and pressures. Under a pressure of about 17 atmospheres at 50°, it assumes the liquid form: it is then limpid, and apparently possessed of a refractive power exceeding that of water; its specific gravity is about 0.9. It does not congeal when cooled down to 0. When a tube containing it was opened under water, it instantly and violently rushed forth under the form of gas. (FARADAY, *Phil. Trans.*, 1823, p. 92.)

Sulphuretted hydrogen gas may be collected over water, though, by agitation, that fluid absorbs nearly thrice its bulk. It has a peculiarly nauseous fetid odour, resembling that of rotten eggs, and so diffusible that a single cubic inch escaping into the atmosphere of a large room, is soon everywhere perceptible by its smell. 100 cubic inches weigh between 36 and 37 grains. Its specific gravity compared with air is as 1.17 to 1; and compared with hydrogen, as 17 to 1. According to Thomson its specific gravity is 1.1805; and 100 cubic inches, reduced to the temperature of 32°, weigh 38.6196 grains. Dumas gives its specific gravity as = 1.1912. It is inflammable, and during its slow combustion, sulphur is deposited, and water and sulphurous acid formed. It extinguishes the flame of a taper. When respired, it proves fatal; and it is very deleterious, even though largely diluted with atmospheric air. According to

the statement of Dupuytren and Thenard, a small bird died immediately in air containing only one 1500th of sulphuretted hydrogen; one 800th killed a middle-sized dog; and a horse perished in an atmosphere containing one 150th. Nausea, vertigo, headach, and a peculiar faintness, are common consequences when an atmosphere even slightly contaminated by sulphuretted hydrogen is breathed for any length of time, and as its escape in the laboratory cannot always be prevented, its effects may be counteracted by the diffusion of a little chlorine, or by sprinkling the room with an aqueous solution of chlorine. It exists in some mineral waters, and is found in foul sewers and in putrid eggs.

The aqueous solution of sulphuretted hydrogen is transparent and colourless when recently prepared, but it gradually becomes opalescent, and if exposed to air it deposits sulphur, and the greater part of the gas escapes. The whole of the gas is evolved by heat. It is an exceedingly delicate test of the presence of most of the metals, with which it forms coloured precipitates. One measure of sulphuretted hydrogen mixed with 20000 measures of hydrogen, carburetted hydrogen, or atmospheric air, produces a sensible discoloration of white lead or of oxide of bismuth, mixed with water, and spread upon a piece of card. In this way we may ascertain the presence, in coal-gas, of extremely small quantities of sulphuretted hydrogen; and may even form an estimate of its proportion, when too minute to be otherwise measured, by comparing the shade of colour with a series prepared for the purpose, by exposing slips of card covered with white lead and water to mixtures of sulphuretted hydrogen and common air, in known proportions. (HENRY, *Elements of Chemistry*.)

Sulphuretted hydrogen slightly reddens infusion of litmus, and moist litmus paper; it is generally classed among the hydracids, and does not, therefore, unite directly with the basic oxides, a metallic sulphuret and water being, as it is presumed, the result of their mutual reaction; it combines with certain sulphurets (basic sulphurets) and forms a class of *sulphur salts*; compounds, according to Graham, strictly analogous to the hydrated oxides, if we substitute sulphur for oxygen.

When one volume of sulphuretted hydrogen is detonated with half a volume of oxygen, water is formed and sulphur precipitated; the whole of the mixed gases being condensed: but when a volume of sulphuretted hydrogen, and a volume and a half of oxygen are inflamed in a detonating tube, one volume of sulphurous acid is produced, and water is formed. Thus the sulphur is transferred to one volume of the oxygen, and the hydrogen to the half volume. Sulphuretted hydrogen may also be decomposed by the Voltaic flame, in the apparatus shown in fig. 219, or by a succession of electric sparks. Its volume is unchanged, but the sulphur is thrown down. This gas, therefore, consists of

Spongy platinum does not effect the combustion of a mixture of sulphuretted hydrogen and oxygen unless free hydrogen be also present.

Chlorine, iodine, and bromine, instantly decompose sulphuretted hydrogen; when they are not in excess sulphur is deposited, and hydrochloric, hydriodic, and hydrobromic acids are formed. Nitric acid poured into the gas occasions a deposition of sulphur, and nitrous acid and water are formed, with considerable elevation of temperature, and occasionally flame. The aqueous solution of the gas is also decomposed by these reagents. Hence the method of preparing hydriodic and hydrobromic acids by passing sulphuretted hydrogen through water in which iodine or bromine is diffused, as already noticed. When sulphuretted hydrogen is mixed with its volume of nitric oxide over mercury, a diminution of bulk ensues, in consequence of the production of water; sulphur is deposited, and nitrous oxide remains in the vessel. When *two* volumes of sulphuretted hydrogen are mixed in an exhausted balloon with *one* of sulphurous acid, they mutually decompose each other, occasioning the production of water, and the deposition of sulphur; if the gases be perfectly dry, the action is slow. According to Thomson, the deposited matter is not sulphur, but a compound of sulphur, oxygen, and hydrogen, which he calls *hydrosulphurous acid*. (*Ann. of Phil.*, xii. 441.) Sulphuric acid also decomposes sulphuretted hydrogen; the results are water, sulphurous acid, and sulphur.

When potassium or sodium are heated in sulphuretted hydrogen, sulphurets of those metals are formed with vivid combustion, and pure hydrogen is liberated. When tin or lead are fused in the gas, they also decompose it, and absorb the sulphur, leaving a volume of hydrogen equal to that of the original gas. Passed over metallic oxides, water and metallic sulphurets are the results. The different oxides effect this decomposition at very different temperatures.

SULPHURETTED HYDROGEN AND AMMONIA. HYDROSULPHURET OF AMMONIA. HYDROSULPHATE OF AMMONIA. SULPHURET OF AMMONIUM. BOYLE'S FUMING LIQUOR. BEGUIN'S SULPHURETTED SPIRIT. $\frac{(s+h)}{(n+3h)}$, or $(hs' + A)$.—When ammonia and sulphuretted hydrogen gas are mixed, white fumes at first appear, which become yellow, and a yellow crystallized compound results. If this be obtained by the condensation of 1 volume of sulphuretted hydrogen and 2 of ammonia, it may be considered as consisting of 1 proportional of each of its components. The best way of combining the gases is to suffer them, previously dried, to pass by separate tubes to the bottom of a flask or bottle immersed in ice; the access of air should be prevented, and the escape of any uncondensed gas provided for by a safety-tube: the crystals thus produced are extremely volatile and deliquescent. When a current of sulphuretted hydrogen gas is passed through an aqueous solution of ammonia, a solution of hydrosulphate of ammonia is also formed.

A compound of sulphuretted hydrogen and ammonia, with excess of sulphur, and holding ammonia in solution, is obtained by distilling a mixture of about four parts of slaked quicklime, two of hydrochlorate of ammonia, and one of sulphur. The following is the disposition of the apparatus for this experiment: (see fig. 250) *a* is a small furnace; *b*, a tubulated earthen retort containing the above materials; *c*, an adapting tube; *d*, a glass balloon for condensing the vapour; *e*, a receiver; *f*, a bottle of water, into which the glass tube, issuing from the upper part of the balloon *d*,

is made to dip about half an inch. The product in the receiver *e*, may be mixed with the water in *f*, and the whole used for washing out the balloon *d*. In its concentrated state, this compound exhales white fumes, and was formerly called *Boyle's fuming liquor*. It is a deep-yellow liquid, smelling like a mixture of sulphuretted hydrogen and

ammonia. When kept in common white glass vessels, it renders them brown or black, in consequence of its action on the oxide of lead which the glass contains. It readily dissolves sulphur. According to Gay Lussac, no ammonia is decomposed in the above operation, but the sulphuretted hydrogen is formed by the union of sulphur with the hydrogen of the hydrochloric acid: the residue in the retort, consisting of sulphate of lime and chloride and sulphuret of calcium, is formed by the union of sulphur with part of the oxygen of the lime to produce sulphate of lime, the evolved calcium being divided between the chlorine and sulphur. Hydrosulphate of ammonia is occasionally used as a test or re-agent. It has been used medicinally as an emetic; and in the dose of from 5 to 8 drops, in the treatment of diabetes.

The neutral hydrosulphate of ammonia resulting from the condensation of 2 volumes of ammonia by 1 volume of sulphuretted hydrogen is a compound of

Ammonia	1	17	50
Sulphuretted hydrogen : :	1	17	50
<hr/>	<hr/>	<hr/>	<hr/>
Hydrosulphate of ammonia	1	34	100

The elements, therefore, which constitute this salt are $(n + 3h) + (s + h)$, and these, upon the ammonium theory, are equivalent to $(n + 4h) + s$, which represents it as a *sulphuret of ammonium*.

BISULPHURET OF HYDROGEN. SUPERSULPHURETTED HYDROGEN. $(h + 2s)$, or HS_2 .—This is a yellow liquid, first described by Berthollet, (*Ann. de Chim.*, xxv.,) formed by dropping a strong solution of bisulphuret of potassium into dilute hydrochloric acid (see *Sulphurets of Potassium*). If the acid be dropped into the sulphuretted solution, sulphuretted hydrogen escapes, and sulphur is precipitated; but proceeding as above directed, the greater part of the sulphur remains united to the hydrogen, and a peculiar yellow liquid is the result. The success of the

experiment depends much upon the state of concentration of the alkaline solution, which should neither be too strong nor too dilute, and should be slightly warm, and stirred during the mixture.

Bisulphuret of hydrogen may also be obtained by boiling equal parts of lime and flowers of sulphur, in five or six parts of water, for about half an hour; when cold, the supernatant brown liquor (containing hydro-sulphuret of lime, with excess of sulphur) is to be poured off, and gradually added to hydrochloric acid, either of its usual strength, or diluted with its bulk of water, taking care to have excess of acid, and to stir the mixture after each addition. Under these circumstances some sulphur is precipitated, and the sulphuretted hydrogen is not evolved, but unites to an additional proportion of sulphur to form the bisulphuret, which gradually subsides in the form of a yellow viscid fluid, which may be kept for some days in the acid liquor, or in dilute hydrochloric acid. Its specific gravity is about 1.7. It is often involved in a coating of sulphur, from which it may be squeezed out by gentle pressure with a glass rod. In water it is slowly resolved into sulphur and sulphuretted hydrogen, and more rapidly by alkaline solutions. At 212° it is rapidly decomposed. Oxide of gold or silver is immediately reduced by it with slight explosion and incandescence. Other substances, such as silica, and the alkaline earths, decompose it, without themselves suffering change; in this, and its property of bleaching, Thenard (*Ann. de Chim. et Phys.*, xlviii. 79,) suggests an analogy between it and peroxide of hydrogen. It has sometimes been regarded as an acid, and hence termed *hydropersulphuric acid*: its elements are

Sulphur	2 . .	32 . .	97

<hr/>			
Bisulphuret of hydrogen	1	33	100

SULPHUR AND NITROGEN do not form any definite compound, though the nitrogen evolved during the decomposition of certain animal substances often seems to contain sulphur. It is possible also, that the purple compound obtained by the action of ammonia on chloride of sulphur, may contain a sulphuret of nitrogen.

§ IX. PHOSPHORUS.

THIS remarkable substance was discovered in 1669 by Brandt, a merchant of Hamburg; he obtained it whilst attempting to extract from human urine a liquid capable of converting silver into gold. (HOMBERG, *Mém. Par.*, x. 84.) Kunckel, an eminent German chemist, aware of the source whence it was obtained, imparted the secret to Kraft of Dresden, who repaired to Hamburg to learn the details of the process, for which he paid Brandt two hundred dollars; but in the mean time Kunckel prepared and exhibited it, and was therefore considered as one of its discoverers. In 1680 an account of it was published in the *Phil. Trans.*, and it became known under the name of *English Phosphorus*, in consequence of the large quantities of it prepared in London, under the

direction of the celebrated Boyle, by his assistant, Godfrey Hankwitz*. In 1737 the process for its preparation was sold by a stranger to the French government, an account of which was published by Hellot, (*Mém. de l'Acad.*, 1737.) It was tedious and disgusting: from five (muids) hogsheads of urine 38 pounds of residue were obtained by evaporation, and this, by four distillations, yielded at most 4 ounces of phosphorus. The process was improved by Margraff, Gahn, and Scheele, and afterwards by Fourcroy and Vauquelin.

Phosphorus, so termed from its property of shining in the dark, (from *φωσ* light, and *φερεειν* to bear,) may be obtained on the small scale, by distilling phosphoric acid, previously fused with one-fourth its weight of powdered charcoal, at a red heat. This mixture is pulverized and put into the coated green-glass or stoneware retort *a* (fig. 251), placed in the furnace *b*; the tube of the retort should be immersed about half an inch into the basin of water, *c*. A great quantity of gas escapes, some of which is spontaneously inflammable, and when the retort has obtained a bright red heat, a substance looking like wax, of a reddish colour, begins to pass over. This, which is impure phosphorus, may be rendered pure by melting it under warm water, and squeezing it through a piece of fine shamoy leather; but great care must be taken that none adheres to the nails or fingers, as it would inflame on taking them out of the water, and produce a painful and troublesome burn. In performing this distillation, a high temperature is required, so that the furnace should be sufficiently capacious to hold a body of charcoal piled up above the retort, which, especially if of earthenware, (which becomes permeable to the vapour of phosphorus, at a red heat,) must be coated with a mixture of slaked lime and solution of borax; this mixture may be laid on with a brush, in two or three successive coats, and forms an excellent *nitrifiable lute*.

Phosphorus may also be obtained by adding solution of nitrate of lead or nitrate of mercury to urine, collecting, washing, and drying the precipitate, and distilling it, as above, with a fourth its weight of powdered charcoal. These precipitates are impure phosphates of lead and mercury; the latter is the easiest of decomposition.

Upon the large scale, phosphorus is most economically obtained from

* The founder of the Chemical Establishment, long known as "Godfrey's," in Southampton Street, Covent Garden. I have a print of this Chemist, by Veretue, which, it is said, he presented to his

customers on taking leave of them to sell phosphorus abroad: he is surrounded with the apparatus used in preparing it. Boyle described the process in a little work, entitled *Aërial Noctiluca*.

the impure superphosphate of lime, procured by acting upon powdered *bone earth* by sulphuric acid. The following is the mode of proceeding:

On twenty pounds of calcined bone, finely powdered, pour twenty quarts of water, and eight pounds of sulphuric acid, diluted with an equal weight of water. Let these materials be stirred together, and simmered for about six hours. Let the whole be then put into a conical bag of linen to separate the clear liquor, and wash the residuum till the water ceases to taste acid. Evaporate the strained liquor, and when reduced to about half its bulk, let it cool. A white sediment will form, which must be allowed to subside; the clear solution must be decanted, and boiled to dryness in a glass vessel. A white mass will remain, which may be fused in a platinum crucible, and poured out into a clean copper dish. A transparent substance is thus obtained, consisting of phosphoric acid, with phosphate, and a little sulphate of lime, commonly known under the name of *glass of phosphorus*. It yields phosphorus when distilled at a bright red heat with charcoal, in the way above described; but when any quantity of phosphorus is to be collected, the retort should be very well and carefully luted, and should have a wide neck terminating in a copper tube, so bent as to dip perpendicularly into a bottle of water, otherwise it will be apt to become plugged up by congealed phosphorus. The phosphorus is generally sufficiently purified by fusing it in hot water, and when cold, cutting it into small pieces, which are put with water into a slightly conical glass tube, and fused by immersion in hot water: on cooling, the phosphorus is withdrawn in the form of a stick. If the phosphorus is much discoloured, it may be cleansed by fusing it first in warm caustic ammonia, and then in alcohol.

“Wöhler recommends instead of the preceding process, to calcine ivory black (which is a mixture of phosphate of lime and charcoal), with fine quartz sand and a little ordinary charcoal, in cylinders of fire-clay, at a very high temperature. Each cylinder has a bent copper tube adapted to it, one branch of which descends into a vessel containing water. The efficiency of this process depends upon the silica acting as an acid and combining with the lime of the phosphate at a high temperature, while the liberated phosphoric acid is decomposed by the carbon.” (GRAHAM.)

When pure, phosphorus is tasteless, colourless, or of a pale buff colour, semitransparent, and flexible at common temperatures, but at 32° , crystalline and brittle. It is also rendered brittle by the presence of less than a 200th part of sulphur. Its specific gravity is 1.770. Its specific heat, as ascertained, apparently with accuracy, by Regnault, is 0.1887, but Dulong and Petit give 0.385 as the average result of their experiments. (*Ann. Chim. & Phys.*, lxxiii. 55.) It is insoluble in water. It melts, when air is excluded, at 105° , undergoing a remarkable dilatation of 0.031 of its volume. If suddenly cooled to 32° , after having been heated to 140° , it sometimes becomes black (THENARD); but if slowly cooled, always remains colourless. “When fused and left undisturbed, it sometimes remains liquid for hours at the usual temperature, particularly when covered by an alkaline liquid.” (GRAHAM.) Under these circumstances its temperature suddenly rises in the act of solidification to about

100°. (DUMAS.) At 550° it boils, air being excluded, and rapidly evaporates in the form of colourless vapour, the density of which, according to Dumas, is 4.355. But phosphorus evaporates, especially if in contact with moisture, at a much lower temperature. The volatility of phosphorus in conjunction with aqueous vapour is well shown by boiling a flask of water containing a piece of phosphorus, over a lamp; the vapour, as it issues from the flask, is beautifully luminous in a dark room. Phosphorus may be purified by careful distillation, but the process is troublesome and dangerous. Dr. Henry gives the following directions for it:—The proper quantity of phosphorus should first be put into the retort, with a sufficient portion of water to cover it. The water must then be made hot enough to melt the phosphorus, which, on cooling, forms a mass, of the shape of the bottom of the retort. When cold, fill the retort with water, and invert it in water. Displace the water by hydrogen gas, forced from a bladder through a bent pipe; keep the finger on the open end of the retort neck; place it in a sand-bath; and immerse the mouth of it in water. Then apply heat very cautiously. A bladder should also be provided, furnished with a stop-cock and pipe, and filled with hydrogen. During the distillation, the gas in the retort is absorbed, and it is necessary to add more from the bladder, otherwise the water will rush into the retort, and occasion an explosion. By distillation in this mode, phosphorus is rendered much purer. In the neck of the retort a substance is condensed of a beautiful red or carmine colour, which is a combination of carbon and phosphorus, or a *phosphuret of carbon*. Thenard observes that phosphorus, however frequently distilled, cannot be freed entirely from carbon, a minute quantity of which does not impair its colour or transparency.

When phosphorus is fused with about half its weight of sulphur, and suffered to cool gradually, a part of the phosphorus separates in rhombic dodecaëdral crystals. (MITSCHERLICH, *Ann. de Chim. et Phys.*, vol. xxiv. p. 270.) It may also be crystallized by slowly cooling a saturated solution of it in naphtha. When exposed to air, it exhales luminous fumes, having a peculiar alliaceous odour: this arises from a slow combustion; hence the necessity of preserving it in water. It has been used in medicine in doses of from one to six grains in the course of the day, dissolved in oil or ether, and is said to be a powerful restorative. In over-doses it is poisonous. (ORFILA, *Traité des Poisons*, ii. Dr. C. W. GREGORY on *New Remedies*.)

Retained for some time in contact with water, phosphorus decomposes it; oxide of phosphorus, and, probably, phosphorous and phosphoric acids are formed, and phosphuretted hydrogen is emitted. Mr. Phillips has observed that these changes are most rapid when light has free access. (*Ann. of Philos.*, vol. v.) According to Berzelius, light, and especially violet light, has the peculiar effect of reddening phosphorus under whatever circumstances it is exposed to its influence; in nitrogen gas, the concentrated solar rays readily fuse it, but in hydrogen and in vacuo, they cause it to sublime in red scales. There are several peculiar circumstances respecting the luminosity and inflammability of phosphorus. When exposed to the air at temperatures above the freezing point, it shines in the dark with a pale blue light, which increases in intensity with the

Lumy.

temperature. This appears to arise from a very slow combustion, attended by the production of acid: it ceases in close vessels as soon as the greater part of the oxygen has been absorbed; and is said not to take place when the air has been artificially dried: in this case the requisite formation of phosphorous acid seems to be prevented. In pure oxygen, phosphorus is not luminous till heated to between 70° and 80° , above which it becomes very luminous, and soon inflames. Oxygen, and most other gases, in which phosphorus has been immersed, acquire its odour, and when mixed with air become slightly luminous. According to Dr. Henry, if a piece of phosphorus be introduced into a vessel of oxygen gas over mercury, at a temperature not exceeding 80° , no perceptible absorption will happen in twenty-four hours; but if, the temperature remaining the same, the pressure be diminished to one-eighth or one-tenth that of the atmosphere, the phosphorus will be surrounded with white vapours, will become luminous in the dark, and will absorb oxygen. Under ordinary pressures, a higher temperature is required for this effect; but if the density of the oxygen be reduced in the above proportion by mixing it with nitrogen, hydrogen, or carbonic acid, the phosphorus becomes luminous. Mr. Graham has shown that the slow combustion of phosphorus in air, is prevented by very small additions of certain gases and vapours. (*Quart. Journ., N. S.*, vol. vi. p. 83.) Thus at the temperature of 66° it is entirely prevented by one volume of olefant gas in 450 volumes of air, by one volume of ether vapour in 150 volumes of air, by one volume of naphtha vapour in 1820, and of oil of turpentine vapour in 4444 volumes of air. This influence is not confined to low temperatures, for a certain admixture of the above vapours will even prevent the oxidation of phosphorus at 200° ; but on allowing such gaseous mixtures to expand, by diminishing the pressure upon them, the phosphorus becomes luminous, and the proportion of foreign gas required to prevent oxidation or slow combustion must be much increased. "The only explanation," Mr. Graham observes, "of this phenomenon which can be offered, is that the gases which exert this influence have an attraction for oxygen, and there is reason to believe are themselves undergoing a slow oxidation at the same time. Now when two oxidable bodies are in contact, one of them often takes precedence in combining with oxygen to the entire exclusion of the other. Potassium is defended from oxidation in air by the same vapours, though to a less degree."

In the vacuum of the air-pump, phosphorus in small pieces, loosely enveloped in cotton, will generally inflame and burn for a time with a pale light: under the same circumstances it more readily kindles if sprinkled with powdered resin or sulphur; alone, it does not inflame. When a stick of phosphorus is sprinkled with lampblack, or powdered animal charcoal, it is also apt to inflame; and, what is curious, when very thin slices of phosphorus are placed upon flannel, wool, lint, fine feathers, or other downy and flocculent substances, they fuse and readily inflame upon the gentlest friction. It seems as if the slow combustion of the phosphorus produced heat enough to fuse it whilst lying upon a very bad conductor. Berzelius remarks, that the water in which phosphorus has been kept in perfectly closed vessels, acquires a luminous property when agitated; this is not the case when air has access.

The temperature at which phosphorus inflames has been variously stated. According to Dr. Higgins, when perfectly dry, a temperature of 60° is sufficient. It easily takes fire by the heat of the hand and slight friction, or when rubbed upon a piece of coarse paper: it requires therefore to be handled and wiped with the utmost caution. Owing to the superficial formation of phosphorous and phosphoric acid, when it burns imperfectly at low temperatures, its further combustion is often prevented: thus, in rubbing a fragment of phosphorus between two pieces of brown paper, a momentary combustion often ensues, and it requires considerable friction to cause it again to inflame; for the same reason it is very difficult to light a piece of paper by the flame of phosphorus, for the paper becomes covered and protected by the acid.

PHOSPHORUS AND OXYGEN.—At a temperature of about 120° , phosphorus instantly takes fire, and burns with intense brilliancy, throwing off copious white fumes of phosphoric acid. If, instead of burning phosphorus with free access of air, it be heated in a confined portion of very rare air, it enters into less perfect combustion, and three compounds of phosphorus with oxygen are the result, each characterized by distinct properties. The first is a red solid, less fusible than phosphorus; the second is a white substance, more volatile than phosphorus; the third, a white and more fixed body. The red solid consists of a mixture of phosphorus and oxide of phosphorus.

OXIDE OF PHOSPHORUS. ($3p + o$).—The white substance with which phosphorus becomes incrustated when kept for some time in water, is generally stated to be an oxide of phosphorus, but Rose has thrown some doubt upon this opinion (POGGEND. xxvii. 565), and Pelouze considers it as a *hydrate* of phosphorus. ($4p + q$.) The red solid is very inflammable, and less fusible and volatile than phosphorus. It is this substance which is generally used in the *phosphoric match-boxes*. To prepare it for this purpose a piece of phosphorus may be put into a small phial, and melted and stirred about with a hot iron-wire, so as to coat its interior. A portion of the phosphorus is thus oxidized by its imperfect combustion, and a small quantity, taken out upon the end of a brimstone match, instantly inflames upon coming into the contact of the air. (NICHOLSON'S *Journal*, vi. 134.)

According to Pelouze (*Ann. de Chim. et Phys.*, L. 83), an oxide of phosphorus is formed by throwing a jet of oxygen gas into phosphorus fused under hot water; vivid combustion ensues, and phosphoric acid is formed, and at the same time a red pulverulent oxide deposited, which is insoluble in water, ether, alcohol, and oils, difficultly inflammable when heated in the air, but instantly burning upon contact of nitric acid. It appears to consist of

						Pelouze.
Phosphorus	3 . . . 48 . . . 85.71	85.5
Oxygen	1 . . . 8 . . . 14.29	14.5
<hr/>						
Oxide of phosphorus	1			56	100.00	100.0

According to Le Verrier, a definite oxide of phosphorus, consisting of

2 atoms of phosphorus + 1 of oxygen, is obtained by exposing small fragments of phosphorus, covered by the liquid chloride of phosphorus, to the action of air: phosphoric acid is formed, and at the same time a yellowish substance, which he regards as a phosphate of the above oxide of phosphorus, and which yields a yellow solution with water. At a temperature of about 176° this solution is decomposed, and a yellow flocculent substance subsides, which is a hydrated oxide of phosphorus, but which, when dried in vacuo over sulphuric acid, loses its combined water. In this state it is a yellow powder insoluble in water, alcohol, and ether. It resists a temperature of 570° without decomposition, but acquires a red colour: it does not burn till heated somewhat beyond the boiling point of mercury. It appears to form feeble combinations with the alkaline salifiable bases.

There are three *acid* compounds of phosphorus and oxygen, which have been termed *hypophosphorous*, *phosphorous*, and *phosphoric* acids.

HYPOPHOSPHOROUS ACID. ($2p + o$) or \underline{p} , was discovered by Dulong in 1816. (*Ann. de Chim. et Phys.*, ii. 141.) It is prepared as follows: Upon 1 part of *phosphuret of barium* pour 4 parts of water, and when the evolution of phosphuretted hydrogen gas has ceased, pour the whole upon a filter. To the filtered liquid add sulphuric acid as long as any precipitate forms: separate the precipitate, which is a compound of sulphuric acid and baryta, and the clear liquor now contains the hypophosphorous acid in solution. When concentrated by evaporation, a sour viscid liquid is obtained, incapable of crystallization, and eagerly attractive of oxygen.

Rose obtained pure hypophosphorous acid by boiling hydrate of baryta with water and phosphorus, till all garlic odour ceased, filtering the liquid and decomposing it by excess of sulphuric acid; separating the precipitate and digesting the clear fluid for a short time with excess of oxide of lead; then filtering the sulphate of lead from the solution of *hypophosphite of lead*, and decomposing the latter by a current of sulphuretted hydrogen. The acid, freed from the precipitate, was concentrated until of sufficient strength.

Hypophosphorous acid appears to consist of 2 atoms of phosphorus and 1 of oxygen.

Phosphorus	2	32	80	Dulong.
Oxygen	1	8	20	73.4
Hypophosphorous acid	1	40	100	26.6
				100.0

But its true atomic weight cannot be accurately determined till the composition of the *hypophosphites* is better known.

When hypophosphorous acid is heated, it is decomposed with the evolution of phosphuretted hydrogen and phosphorus; phosphoric acid is the residue: in its ordinary state, therefore, it evidently contains combined water, and indeed it yields a crystallizable hydrate by very cautious evaporation. It is a powerful deoxidizing agent. In combination with bases it forms *hypophosphites*; they are soluble in water, and many of them in alcohol; they are decomposed by a red heat: they are mostly deliquescent and uncrystallizable. (DULONG.)

HYPOPHOSPHITE OF AMMONIA.—This salt is extremely soluble, very deliquescent, very difficultly crystallizable, and soluble in alcohol.

PHOSPHOROUS ACID. ($p + 1\frac{1}{2}o$) or \hat{p} .—The volatile white substance above mentioned as one of the products of the combustion of phosphorus in rarefied air, is this acid in a dry state: by burning phosphorus in a tube with very limited access of air, and caution as to temperature, as for instance, by placing a piece of phosphorus near one end of a tube three feet long, inflaming it, and gently propelling air through the tube, it may be collected in the form of a white volatile powder, which, when exposed to air, rapidly absorbs moisture, becomes hot, inflames, and burns into phosphoric acid. Heated in close vessels it gives off phosphorus and leaves phosphoric acid. It rapidly dissolves in water, has a sour taste, reddens vegetable blues, and combines with certain of the salifiable bases to form salts called *phosphites*. When acted upon by such of the metallic oxides as readily part with their oxygen, it is converted into phosphoric acid, and the oxide is reduced.

The phosphorous acid in combination with a definite proportion of water, forming what Sir H. Davy termed *hydrophosphorous acid*, is obtained by mixing *protochloride of phosphorus* with water: a mutual decomposition of the liquids ensues, and hydrochloric acid and phosphorous acid result; the former is easily driven off by heat, and, on carefully evaporating the remaining solution, a crystallizable compound is obtained, of a sour taste, and very soluble in water, which by heat is resolved into phosphoric acid and hydroguret of phosphorus. (See *Phosphuretted Hydrogen*.) A current of chlorine passed through phosphorus fused under hot water, first converts it into a chloride, which afterwards reacts on the water: on evaporation, the hydrophosphorous acid remains.

The slow and spontaneous combustion of phosphorus in a moist atmosphere, as when phosphorus is suffered to deliquesce upon a funnel, is attended by the production of a sour liquid, which may thus be gradually collected; it appears to be a mixture of hydrated phosphorous and phosphoric acids. Dulong termed it *phosphatic acid*.

If the equivalent of the phosphorous acid be deduced from its saturating power, the phosphites being regarded as constituted of one atom of acid united to one atom of base, it will consist of

				Davy.	Berzelius.	Dulong.
Phosphorus . . .	1	16	57.14	56	56.524	57.18
Oxygen . . .	$1\frac{1}{2}$	12	42.86	44	43.476	42.82
Phosphorous acid	1	28	100.00	100	100.000	100.00

PHOSPHITE OF AMMONIA. ($\hat{p} + A.$)—This salt is obtained in deliquescent prismatic crystals by saturating phosphorous acid with carbonate of ammonia. When heated it gives out ammonia, and leaves phosphorous acid and water, which, on the further application of heat, is decomposed, and hydrated phosphoric acid remains. (ROSE, POGG., *Ann.*, ix. 28.) According to Dr. Thomson, the constituents of the crystals are

Ammonia	1	17	27.0
Phosphorous acid . . .	1	28	44.4
Water	2	18	28.6
Phosphite of ammonia	1	63	100.0

PHOSPHORIC ACID. ($p + 2\frac{1}{2}O$) or p' . $2P^5O$, or \ddot{P} , TURNER. ($p + 5O$) or PO_5 , GRAHAM*.—This acid may be formed by the direct combustion of phosphorus in excess of oxygen; intense heat and light are produced, and white deliquescent flocculi line the interior of the receiver. It is produced in the same way by burning phosphorus under a dry bell-glass in atmospheric air. For this purpose, a piece of phosphorus, in a watch-glass or small porcelain capsule, may be placed upon a plate of glass, and covered over with a tall receiver; when inflamed, it burns at first furiously, but the combustion gradually subsides for want of oxygen, and may be renewed by gently lifting the receiver off the glass plate: thus the whole of the phosphorus may be gradually burned, and it forms a quantity of dense smoke, which subsides in the form of snowy flakes: this is *Anhydrous Phosphoric Acid*, mixed sometimes with a little phosphorous acid: if water be dropped upon it, it produces a hissing noise, and much heat is evolved, but it is some time before the whole dissolves into a clear liquid. The solution is intensely sour. In its anhydrous state this acid appears to be perfectly fixed, but in the air, or wherever aqueous vapour is present, it sublimes away, apparently in the state of hydrate.

Phosphoric acid may also be obtained by acting upon phosphorus by nitric acid; in this case, if the action be at all intense, a portion of ammonia is at the same time produced, which is found in the state of phosphate of ammonia in solution. About six parts of nitric acid, specific gravity 1.4, are introduced into a tubulated retort placed in a sand-heat, with a tubulated receiver luted on to it, the stopper of which should be open. When the acid is warm, drop into it gradually and carefully one part of phosphorus in small pieces; red nitrous vapour is instantly disengaged, and when its evolution ceases, put the stopper loosely into the receiver, and distil till the residue in the retort acquires the consistence of syrup; pour it into a platinum crucible, and give it a dull red heat; it fuses, and concretes on cooling, into a transparent substance, which is *hydrated phosphoric acid*, and which retains water with great avidity, even at red heat, and at very high temperatures slowly volatilizes; in this state it is sometimes called *glacial phosphoric acid*. In the *London Pharmacopæia* diluted phosphoric acid is directed to be obtained by distilling a mixture of 4 fluid ounces of nitric acid and 10 of water, off an ounce of phosphorus: when 8 fluid ounces have passed over they are to be returned into the retort and again distilled over; the remaining liquor is then to be evaporated in a platinum capsule and diluted with distilled water, so as to make up 28 fluid ounces. The specific gravity of this dilute acid is 1.064, and 100 grains of it are saturated by 42 of crystallized carbonate of soda: it appears to contain about 10 per cent. of acid.

* Professor Graham, to whom we are indebted for an elaborate investigation into the constitution of the modifications of this acid and the atomic composition of the phosphates, doubles the equivalent of phosphorus, and represents this acid, therefore, as a compound of 1 atom

of phosphorus and 5 of oxygen. Dr. Turner, on the other hand, represents it as constituted of 2 atoms of phosphorus and 5 of oxygen, in this case retaining the equivalent 16 (or 15.7) for phosphorus, whereas Graham uses 31.4 (nearly 16×2) as the equivalent of phosphorus.

Another mode of obtaining phosphoric acid, consists in heating *phosphate of ammonia* to redness, which may be economically prepared for this purpose by saturating the impure phosphoric acid obtained from calcined bones (p. 484) by carbonate of ammonia.

The hydrated phosphoric acid, when pure, readily dissolves in water; it deliquesces upon exposure to humid air into an intensely sour liquid, of a specific gravity = 2. It does not corrode the skin like nitric and sulphuric acids. Dr. Turner remarks (*Elements of Chemistry*), that it may be distinguished from all other acids by the following circumstances: that when carefully neutralized by pure carbonate of soda or potassa, it forms a solution in which no precipitate, or change of colour, is produced, when a stream of sulphuretted hydrogen gas is passed through it; but which is precipitated *white* by a solution of acetate of lead, and *yellow* by nitrate of silver: the first precipitate, the phosphate of lead, dissolves completely on the addition of nitric or phosphoric acid; the second, the phosphate of silver, is dissolved by both these acids and by ammonia.

It has been satisfactorily proved by the accurate researches of Berzelius and of Dulong, that the ratio of the oxygen in the phosphorous acid is to that in the phosphoric acid as 3 to 5; and assuming these acids to consist respectively of one atom of phosphorus and three of oxygen, and one atom of phosphorus and five of oxygen, the number 32 (or thereabout) would be the equivalent of phosphorus, and 72 that of the phosphoric acid; but the adoption of this latter number would oblige us to consider the *neutral* phosphates as constituted of *one* atom of acid and *two* atoms of base, which is contrary to all analogy; the fact is, that 36 is the equivalent of the phosphoric acid, and 28 that of the phosphorous acid; hence the necessity of considering the latter, as above stated, a compound of 1 atom of phosphorus and $1\frac{1}{2}$ of oxygen; and upon the same principle the anhydrous phosphoric acid will consist of

				Davy.	Berzelius.	Dulong.	Rosc.
Phosphorus . . .	1	16	44.44	42.6	43.823	44.8	46.5
Oxygen . . .	$2\frac{1}{2}$	20	55.56	57.4	56.177	55.2	53.5

The *glacial phosphoric acid*, or the hydrated acid exposed to a heat at which it no longer loses water, but begins to sublime or evaporate without decomposition, appears to consist of

				Dulong.
Phosphoric acid . . .	1	36	80	79.4
Water	1	9	20	20.6
Glacial phosphoric acid	1	45	100	100.0

Mr. Graham observes (*Elements of Chemistry*) that when phosphoric acid is dissolved in water the compound is marked by an unusual inconstancy of character, arising from the circumstance that it is not actual phosphoric acid, but a hydrate of that acid, which is soluble, as indeed is also the case with sulphuric acid; but the peculiarities of the phosphoric acid arise out of the circumstance that it forms *three* definite combinations with water, each of which is soluble without change, and these *phos-*

phates of water exhibit properties so distinct that they might be supposed to contain distinct acids. When the anhydrous acid obtained by burning phosphorus in dry air is thrown into water, it produces an indefinite mixture of the three hydrates, but each of them may be obtained pure by a particular process, in reference to which I shall adopt Mr. Graham's nomenclature.

1. *Terhydrate, or Tribasic Phosphate of Water.* $3\text{HO} + \text{PO}_5$. ($= 1\frac{1}{2}(h+o) + (p+2\frac{1}{2}o)$ of our equivalents; or 1 atom of anhydrous phosphoric acid and $1\frac{1}{2}$ of water.)—This compound is obtained by adding to a warm solution of the common phosphate of soda of pharmacy (which should be re-crystallized in order to purify it) a solution of acetate of lead, so long as it occasions a precipitate: the phosphate of lead which falls is then washed, diffused in cold water, and decomposed by a stream of sulphuretted hydrogen; the liquor is then heated and filtered; it is very sour and contains the terhydrate of phosphoric acid. "The characters of this solution are to give a *yellow* precipitate with nitrate of silver, to yield the common phosphate of soda when neutralized by carbonate of soda, to form salts which have invariably three atoms of base to one of phosphoric acid, and to be unalterable by boiling its solution, or keeping it for any length of time. The class of salts which this hydrate forms are the old phosphates which have been long known, and it is convenient to allow them to be particularly distinguished as the *phosphates*, or common phosphates." In the language of our equivalents it is a *sesquihydrate*.

2. *Deutohydrate of Phosphoric Acid, or Bibasic Phosphate of Water.* $2\text{HO} + \text{PO}_5$. ($= (h+o) + (p+2\frac{1}{2}o)$ of our equivalents; or 1 atom of anhydrous phosphoric acid and 1 of water.) *Pyrophosphoric Acid.*—In the year 1826, Dr. Clark, of Glasgow, observed, that when *phosphate of soda* had been heated to redness, its solution, instead of throwing down a yellow precipitate with nitrate of silver, produced a *white* precipitate. (BREWSTER'S *Edin. Journal*, vii. 298.) Professor Stromeyer had also observed the same fact, and in 1830, communicated a paper on the subject to the Royal Society of Göttingen. (*Ann. de Chim. et Phys.*, xliii. 364.) The phosphoric acid, after it has been exposed for some time to heat, yields, when saturated with bases, salts possessed of certain peculiarities, which have hence been termed *pyrophosphates*. If a solution of such pyrophosphate of soda be precipitated by acetate of lead, the precipitate washed and decomposed by sulphuretted hydrogen as before, an acid liquor is obtained, which holds the deutohydrate of phosphoric acid in solution; it must not be heated to expel the sulphuretted hydrogen, but left in a shallow basin for 24 hours to allow the escape of that gas. The acid thus obtained gives a *white* precipitate with nitrate of silver; when neutralized by carbonate of soda it gives Dr. Clark's pyrophosphate of soda, and all the salts which it forms have uniformly 2 atoms of base (in reference, that is, to Mr. Graham's equivalents). These salts may by way of distinction, be denominated *pyrophosphates*. A dilute solution of the pyrophosphoric acid may be preserved without change, but if boiled it passes into the terhydrate (or sesquihydrate of our equivalents).

3. *Protohydrate of Phosphoric Acid.* $\text{HO} + \text{PO}_5$ (GRAHAM), or

$(h + o) + 2(p + 2\frac{1}{2}o)$, that is, 2 atoms of anhydrous acid and 1 of water, according to our equivalents. This modification of the phosphoric acid is obtained by heating biphosphate of soda to redness, dissolving it in water, and decomposing the solution by acetate of lead: the precipitate is then to be treated by sulphuretted hydrogen as before, and the resulting acid liquor contains Graham's protohydrate of phosphoric acid. The biphosphate of soda for this purpose is prepared by adding a solution of the terhydrate of phosphoric acid to a solution of the common phosphate of soda, till a drop of the latter is no longer precipitated by chloride of barium: the biphosphate of soda, now in solution, can only be crystallized in cold weather. "This acid is characterized," says Mr. Graham, "by producing a white precipitate in solution of albumen; and in solutions of the salts of earths and metallic oxides, precipitates which are remarkable semifluid bodies, or soft solids, without crystallization. All these salts contain only one atom of base to one of acid, like the protohydrate of the acid itself. (The trivial name *metaphosphates* was applied to the class by myself to mark the cause of the retention of peculiar properties by their acid, when free and in solution, namely, that it was not then simply phosphoric acid but phosphoric acid *together with water*. *Phil. Trans.*, 1833, p. 253.) This is the least stable of the hydrates of phosphoric acid, being converted rapidly by the ebullition of its solution into the terhydrate. If the terms *metaphosphoric* and *pyrophosphoric acid* are employed at all, it is to be remembered that they are applicable to the proto and deutohydrates, and not to the acid itself, which is the same in all the hydrates. But to prevent the chance of misconception, *metaphosphate of water* and *pyrophosphate of water* might be substituted for these terms."

We shall find in the sequel that the three hydrates of phosphoric acid form three classes of phosphates, the quantity of base which unites to the acid in the humid way being regulated by the proportion of water previously combined with the acid, and which is replaced by the fixed base, affording, as Mr. Graham observes, a good illustration of the formation of compounds by substitution. Thus, "The protohydrate of phosphoric acid combines with no more than one, and the deutohydrate with no more than two, proportions of soda, although three or a larger number of proportions of alkali be added to it: the excess of alkali remains free." Mr. Graham's further remarks upon this curious and intricate subject I must leave till the other salts of the phosphoric acid are individually before us; in the mean time, I must again remind the student of the discrepancy between Mr. Graham's equivalents and those which we have adopted, in respect to the phosphoric acid, *two* of our equivalents of that acid being = to *one* of his, whilst our equivalents for water agree; and although Dr. Turner and Mr. Graham agree in their equivalent number for phosphoric acid, they give different views of its atomic constitution, Turner representing it as constituted of 2 atoms of phosphorus and 5 of oxygen, (simply, therefore, doubling our numbers,) whilst Graham doubles the number for phosphorus, and therefore represents phosphoric acid as constituted of 1 atom of phosphorus and 5 of oxygen. The following is a comparative statement of these different views:—

GRAHAM.		TURNER.		BRANDE.	
	Symbol.	Equivalent.	Symbol.	Equivalent.	
Phosphorus	P	31.44	P	15.72	p 16

PHOSPHATE OF AMMONIA. ($p' + A.$)—The mutual action of anhydrous phosphoric acid and ammonia has not been studied: they probably give rise to an *amide*. The neutral phosphate of ammonia may be obtained pure by saturating phosphoric acid with ammonia or carbonate of ammonia and carefully evaporating, so as to avoid the production of an acid salt. It may also be formed by adding carbonate of ammonia to the acid phosphate of lime obtained from bone earth (p. 484), till no further effervescence or precipitation of phosphate of lime follows, filtering and evaporating, taking care, however, to leave slight excess of ammonia: the solution left to itself deposits the salt. Its primary form is an oblique rhombic prism, the smaller angle of which is $84^{\circ} 30'$. Its prisms are often terminated by dièdral summits. (MITSCHERLICH, *Ann. de Chim. et Phys.*, xix. 382.) The crystals are efflorescent, and by long exposure become *biphosphate* from loss of ammonia: they taste saline, cooling, and bitterish. This salt is soluble in 4 parts of cold water. When heated it melts, and losing ammonia leaves hydrated phosphoric acid. It exists in the urine of carnivorous animals. This salt has not been accurately analyzed, but it probably consists of

					Mitscherlich.

BIPHOSPHATE OF AMMONIA. ($2p' + A.$)—This salt is obtained by adding phosphoric acid to a solution of the phosphate of ammonia till it strongly reddens litmus paper, and ceases to occasion a precipitate in a dilute solution of chloride of barium. When the solution is concentrated it yields crystals, the primary form of which is an octoëdron with a square base; but they are most commonly right square prisms terminated by the primary faces. They are less soluble than the preceding salt, and permanent in the air: when heated they fuse and froth up, ultimately leaving hydrated phosphoric acid. They consist of

Biphosphate of ammonia	1		116		100.00

Gay Lussac has recommended the application of phosphate of ammonia to render muslin, and similar articles of clothing, to a considerable extent incombustible. The goods are immersed in a solution of equal parts of phosphate and hydrochlorate of ammonia of a due strength, and then dried; upon applying flame to them, it will be found that they are burned with great difficulty, and cannot be consumed with flame, in consequence of the prevention of the access of oxygen by the glazing which the salts form at high temperatures.

When considering the basic oxides, the constitution of the *phosphates* will be more particularly adverted to. Mr. Graham's views respecting the peculiarities of these salts, as formed by the three hydrates of phosphoric acid, will be found in his *Elements of Chemistry*, p. 349.

PHOSPHORUS AND CHLORINE.—These elements unite in two proportions, forming two definite compounds, the *chloride*, or *sesquichloride*, and the *perchloride* of phosphorus.

PROTOCHLORIDE OF PHOSPHORUS. SESQUICHLORIDE OF PHOSPHORUS. (TERCHLORIDE OF PHOSPHORUS. GRAHAM.) $(p + 1\frac{1}{2}c)$ or $(2p + 3c)$.—This compound is procured by distilling a mixture of phosphorus and *perchloride of mercury*; or, what amounts to the same thing, by passing the vapour of phosphorus over perchloride of mercury in a heated glass tube, terminating in a cooled receiver. It is also formed by passing chlorine first through a cold flask, then through a tube containing fragments of fused chloride of calcium, and thence into a tubulated retort, slightly warmed, and containing phosphorus, from which the sesquichloride, as it is formed, gradually distils over into a cooled receiver. (GMELIN.)

When first obtained, this compound generally holds a little phosphorus in solution, which gives it a reddish colour; this is in time deposited, and it becomes limpid and colourless; or it may at once be purified by slow distillation; it requires to be cautiously excluded from the action of the air. It has a suffocating odour. Its specific gravity is 1.45. Exposed to the air it exhales acid fumes: it does not change the colour of *dry* vegetable blues, but becomes powerfully acid upon the least acquisition of moisture. Its vapour is combustible. Chlorine converts it into perchloride of phosphorus. It acts upon water with great energy, and produces hydrochloric and *phosphorous* acids, as above stated (page 489).

It appears from the analyses of Davy and of Berzelius, that this chloride corresponds in composition to the phosphorous acid; it is therefore a sesquichloride of phosphorus, and consists of

						Davy and Berzelius.

PERCHLORIDE OF PHOSPHORUS. $(p + 2\frac{1}{2}c)$ or $(2p + 5c)$.—When phosphorus is submitted to the action of chlorine in excess, it burns with a pale yellow flame, and produces a white, flaky, and volatile compound, which attaches itself to the interior of the vessel, and which is the *perchloride of phosphorus*. It may be conveniently formed in the exhausted retort, as described at p. 364. It was long mistaken for phosphoric acid, but its easy volatility is alone sufficient distinction, for it rises in vapour at 200° . It is fusible under pressure, and crystallizable in transparent prisms; it is a non-conductor of electricity; it reddens dry litmus paper, in consequence, as Berzelius supposes, of its acquiring hydrogen and oxygen from the decomposition of the paper. It fumes in the air, and when brought into the contact of water, a mutual decomposition is immediately effected, and phosphoric and hydrochloric acids result. When passed through a red-hot porcelain tube with oxygen, phosphoric acid is produced and chlorine evolved, which shows that oxygen, at that temperature, has a stronger attraction for phosphorus than chlorine. Potassium, heated in its vapour, burns with great brilliancy:

the metallic oxides decompose it with the production of metallic chlorides and phosphates.

The perchloride of phosphorus consists of

AMMONIA AND CHLORIDE OF PHOSPHORUS.—*The action of ammonia on the chlorides of phosphorus* is very remarkable, and was first observed by Davy, and since elaborately examined by H. Rose. When ammonia is admitted into an exhausted retort containing the perchloride of phosphorus, the gas is rapidly absorbed with much heat, and a compound is produced which, according to Davy, is insoluble in water, indecomposable by acid or alkaline solutions, and has characters analogous to an earth. The action of ammonia on the sesquichloride is attended by the production of the same compound, and the separation of a portion of phosphorus. (*Elements*, p. 291.) According to H. Rose, (*über eine Verbindung des Phosphors mit dem Stickstoff*;) the most definite action of ammonia is on the sesquichloride of phosphorus. (POGGEND., xxiv. 308.) This liquid, when freed from dissolved phosphorus by repeated distillation, and subjected (surrounded by a freezing mixture so as to prevent elevation of temperature and consequent deposition of phosphorus) to the gradual action of excess of ammonia, forms with it a perfectly white compound, which is entirely, though very slowly, soluble in water, and is so constituted, as to yield in this process, neutral hydrochlorate and phosphite of ammonia. When heated in the air, it gives off hydrochlorate of ammonia, and leaves an insoluble reddish-brown substance, which, when heated, becomes white, but again brown as it cools. To obtain the fixed residue in a pure state, freshly prepared *ammonio-sesquichloride of phosphorus* must be cautiously heated to redness out of the contact of air: this is best done by putting it into a sufficiently large tube of difficultly fusible glass, and passing over it at a red heat a stream of carbonic-acid gas dried by contact of chloride of calcium: the operation must be patiently carried on till no traces of hydrochlorate of ammonia are evolved. With these precautions, the substance which remains is a light white powder, and though formed of highly-volatile substances is, when excluded from air and moisture, fixed and infusible at a red heat: heated in contact of the air and its moisture, it evolves white fumes of phosphoric acid, and becomes slowly oxidized without flaming: if thus heated in a platinum crucible, the metal is much corroded. Exclusively of its fixedness out of the contact of air, the most remarkable property of this substance is its indifference to the strongest re-agents. Concentrated nitric acid very slowly converts a portion of it into phosphoric acid, and concentrated sulphuric acid produces the same change with the evolution of sulphurous acid; but the dilute acids and alkaline solutions, and chlorine, sulphur, and carbonic acid, have no action upon it even when heated. It is, on the contrary, energetically acted upon when fused with caustic potassa; ammonia is evolved, and the residue is soluble in water. It is decomposed when heated with hydrate of baryta, with intense ignition:

it is also decomposed by fusion with the carbonated fixed alkalis, and with their nitrates. The action of dry hydrogen gas upon this compound at a red heat is very remarkable; no trace of water is formed, phosphorus is evolved, and distils off, and on conducting the gaseous products into water, ammonia is found in solution. From this result, and from other evidence adduced by Rose, this compound apparently consists of phosphorus and nitrogen; it is a true *phosphuret of nitrogen*; and from the analytical details given at length in the essay I have quoted, it appears that 100 parts of the ammonio-sesquichloride, yield an average product of 21·27 of this phosphuret of nitrogen, and that it consists of

					Rose.
Phosphorus . . .	1	..	16	..	53·3
Nitrogen . . .	1	..	14	..	46·7
					52·56
					47·44
Phosphuret of nitrogen	1		30		100·0
					100·00

It is obvious that there is no analogy between this compound and those of nitrogen with chlorine and iodine; indeed, its properties are diametrically opposed to those detonating and easily-decomposable substances: it presents a remarkable but not solitary instance of the production of a fixed substance from the union of highly volatile elements. Its atomic constitution as given above, closely agrees with the experimental result, but is not consistent with the other combinations of phosphorus.

PHOSPHORUS AND IODINE.—When these substances, perfectly dry, are brought together in an exhausted vessel and gently heated, they act violently, evolving heat but no light, and form orange-coloured, red, or black compounds, according to their relative proportions. When one part of phosphorus and about twelve of iodine are fused together, the compound is reddish-brown, very fusible, and appears to be a *sesquiodide of phosphorus* ($p + 1\frac{1}{2} i$), for it is decomposed by water, and resolved into hydriodic and phosphorous acids: it therefore consists of

Phosphorus	1	..	16	..	7·8
Iodine	$1\frac{1}{2}$..	188	..	92·2
Sesquiodide of phosphorus	1		204		100·0

PERIODIDE OF PHOSPHORUS. ($p + 2\frac{1}{2} i$).—When one part of phosphorus is fused with nearly 40 of iodine, a black and less fusible compound results, which is resolved by water into hydriodic and phosphoric acid, and which, therefore, apparently consists of

Phosphorus	1	..	16	..	4·88
Iodine	$2\frac{1}{2}$..	12	..	95·12
Periodide of phosphorus	1		328		100·00

PHOSPHORUS AND BROMINE.—According to M. Balard there are two bromides of phosphorus. When phosphorus and bromine are mixed in a flask filled with carbonic acid, they act intensely upon each other: heat and light are evolved, and a yellow crystalline substance rises to the upper part of the flask, whilst a liquid remains at the bottom. The latter is the *sesquibromide*, it is volatile, and emits pungent fumes when

exposed to air. Water resolves it into hydrobromic and phosphorous acids. The crystalline *perbromide* is converted, by a gentle heat, into a red liquid, and at a higher temperature into red vapour. It emits fumes when exposed to air, and, acted upon by water, forms hydrobromic and phosphoric acid.

Both these bromides are decomposed by chlorine, with the evolution of bromine and the formation of chloride of phosphorus. Iodine, on the contrary, does not decompose them; but bromine decomposes the iodides of phosphorus.

From the action of these bromides on water, there can be little doubt that the former is a *sesquibromide of phosphorus* ($p + 1\frac{1}{2}b$); and that the composition of the *perbromide* corresponds with that of the phosphoric acid and of the perchloride, being ($p + 2\frac{1}{2}b$.)

FLUORIDE OF PHOSPHORUS. ($p + 1\frac{1}{2}f$).—By distilling fluoride of lead or mercury with phosphorus, Davy obtained a fuming liquid, resolved by the action of water into hydrofluoric and phosphorous acids.

PHOSPHORUS AND HYDROGEN; PHOSPHURETTED HYDROGEN; HYDROGURET OF PHOSPHORUS.—Phosphorus may be heated, and even sublimed, in hydrogen gas, without the formation of any definite compound, although, under such circumstances, the gas retains a portion of the vapour of phosphorus, acquiring its peculiar odour, and becoming luminous in the dark when mixed with atmospheric air. When phosphorus is presented to *nascent* hydrogen, two gaseous compounds result. The one inflames spontaneously upon the contact of the atmosphere. This may be procured by heating phosphorus in a solution of caustic potassa; or by acting upon *phosphuret of lime* by dilute hydrochloric acid. In the former case about a quarter of an ounce of phosphorus should be introduced into a small retort, capable of holding about four ounces of water; it should then be completely filled with a moderately-strong solution of potassa, and the beak being placed under the shelf of the pneumatic apparatus, the heat of an Argand lamp carefully applied till it boils: gas will gradually be generated, so as to expel a portion of the alkaline solution, and ultimately to bubble up through the water. Upon coming into contact with the air, the bubbles inflame with a slight explosion; and if the atmosphere is still, each as it bursts produces a beautifully-expanding ring of smoke, in consequence of the sudden formation of phosphoric acid and water. If the retort, in which the gas is generated, contain common air, the first bubbles burn within the vessel, and the retort is frequently broken by the percussion, or by the rush of cold water from the trough, caused by the sudden expansion and subsequent contraction of the air within, an accident prevented by filling the retort with the liquid.

For obtaining this gas by the second process, Dr. Thomson gives the following directions:—Fill a small retort with water, acidulated by hydrochloric acid, and then throw into it a quantity of phosphuret of lime in lumps. Plunge the beak of the retort under water, and place over it an inverted jar filled with that liquid. Phosphuretted hydrogen gas is extricated in considerable quantity, and soon fills the glass jar. Half an ounce of phosphuret of lime yields about 70 cubic inches of this gas. (*Inorg. Chem.*, i. 251.)

This gas was discovered by Gengembre in 1783; it is colourless, has a nauseous odour like onions, a very bitter taste, and inflames when mixed with air, a property which it loses by being kept over water: water takes up about two *per cent.* of this gas, and acquires a bitter taste, and the smell of onions; but the solution has no acid properties like that of sulphuretted hydrogen. When the gas is retained in dry vessels, or over mercury, and carefully excluded from light, it may be kept some time without alteration: but, in the contact of water, and exposed to light, it soon deposits a red film, without changing its volume, and loses the property of spontaneous inflammability. It has been asserted, that in this case the gas deposits half of its phosphorus, and that a definite *subphosphuretted hydrogen* remains; but this statement requires further proof. Houton Labillardière has remarked, that bubbles of phosphuretted hydrogen sent up into a portion of common air standing over mercury, do not inflame when the air is compressed, or when the mercury is at the same level within and without the vessel; but that explosion immediately ensues when the confined air is rarefied by lifting up the jar, so that the column of mercury within may be above that without. When bubbles of phosphuretted hydrogen are sent up into a jar of oxygen, they burn with greatly increased splendour; in chlorine, too, they burn with a beautiful pale blue light, forming hydrochloric acid and perchloride of phosphorus. In a narrow tube it may be mixed with oxygen without exploding, in which case it is deprived of its phosphorus. It burns when thrown up into nitrous oxide.

The specific gravity of this gas, according to Dumas, is 1.761, (*Ann. de Chim. et Phys.*, xxxi. 149,) according to Thomson (*Inorg. Chem.*, i. 252), it is 1.77. When heated with corrosive sublimate, hydrochloric acid gas is formed, equal to three times the volume of the phosphuretted hydrogen decomposed, whence it appears to contain, in the 100 measures, 150 measures of hydrogen; Dumas states the weight of the phosphorus to that of the hydrogen as 15.9 to 1, numbers which closely approximate to 16 and 1, or one equivalent of each of its components.

SESQUIHYDROURET OF PHOSPHORUS; HYDROPHOSPHORIC GAS. ($p + 1\frac{1}{2}h$.)—This compound of phosphorus and hydrogen was discovered by Sir H. Davy, in 1812. It is procured by heating the solid *hydrate of phosphorous acid*, or *hydrophosphorous acid* (p. 489), in a small retort. The gas must be collected over mercury, for water absorbs one-eighth its volume. It is not spontaneously inflammable, but explodes when heated with oxygen. It inflames spontaneously in chlorine. Its smell is less disagreeable than the former.

Both this and the former gas frequently contain free hydrogen, the relative proportion of which may be ascertained by agitation with a cold saturated solution of persulphate of copper, which absorbs the phosphuretted hydrogen, and leaves the pure hydrogen. Dumas infers from the action of perchloride of mercury on this gas, that 100 measures yield 150 of hydrogen. Dr. Turner, on the authority of Dumas and of Buff (*Ann. de Chim. et Phys.*, xli.), considers 100 measures of this variety of phosphuretted hydrogen as constituted of 150 of hydrogen gas, and 25 of the vapour of phosphorus (*Elements of Chem.*), and hence as

		Grains.
150 cubic inches of hydrogen weigh	3.1977
25 " phosphorus vapour	33.5425
100 " phosphuretted hydrogen gas should weigh		36.7402

The calculated density of a gas so constituted should be 1.1853.

It is now generally assumed that the spontaneously inflammable phosphuretted hydrogen derives its peculiarities from the presence of something extraneous, or according to Leverrier (*Ann. C. & P.*, LX. 174), to a gaseous compound of phosphorus and hydrogen ($p+h$), which is decomposed by light. Mr. Graham ascertained that Davy's hydrophosphoric gas was not rendered spontaneously inflammable by the presence of phosphorus vapour, and that the spontaneously inflammable gas was deprived of that property by very minute portions of certain combustible bodies, such as potassium, and the vapour of ether and essential oils; and lastly, that the property was communicated to either gas by the addition of a very minute quantity of nitrous acid vapour, varying from 1-1000th to 1-10,000th of the volume of the gas.

Grotthus has described a liquid compound of phosphorus and hydrogen, analogous probably to the corresponding combination of sulphur, (and, if so, *biphosphuret of hydrogen*,) obtained by boiling phosphorus in an alcoholic solution of potassa. The phosphorus liquifies, and remains fluid when cold; if boiled in water, phosphuretted hydrogen is evolved, but no phosphoric acid is formed, nor is the water decomposed; and phosphorus, which concretes as usual, remains behind. According to Magnus, when phosphuret of potassium is thrown into water, a compound of phosphorus and hydrogen precipitates in the form of a yellow powder. Phosphuretted hydrogen combines with several of the perchlorides, and with the perchloride of tin it forms a compound which is decomposed with the escape of a non-inflammable gas by water, but of a spontaneously inflammable gas by solution of ammonia.

Common phosphorus always yields a trace of hydrogen or of phosphuretted hydrogen, which it evolves when in the act of combining with some of the metals, and Davy found that by acting on fused phosphorus by the voltaic spark, small portions of hydrogen were given off.

PHOSPHORUS AND NITROGEN; PHOSPHURET OF NITROGEN: (see *action of ammonia on chloride of phosphorus*, p. 497.)

AMMONIURET OF PHOSPHORUS.—According to Berzelius, when phosphorus is exposed to ammonia standing over mercury, a *phosphuret of ammonia* is produced, of a dark colour, and pulverulent texture: its properties have not been examined. Bineau could not succeed in obtaining this compound. (*Ann. C. & P.*, LXVII. 229.)

PHOSPHORUS AND SULPHUR; PHOSPHURET OF SULPHUR; SULPHURET OF PHOSPHORUS.—These substances may be united by fusion in an exhausted flask, or under water; in the latter case they combine gradually as soon as the phosphorus is melted, but the heat must be cautiously applied, as the water is sometimes suddenly decomposed with explosive

violence. Mr. Faraday (*Quarterly Journal*, iv. 361) melted 5 parts of sulphur with 7 of phosphorus and agitated the compound in liquid ammonia, by which the reddish-brown colour was removed and a pure fluid of a light-yellow colour, and semitransparent, remained. It retained its fluidity when cooled down to 20° , and was perfectly liquid at 32° . On remaining for some weeks in a bottle of water it deposited crystals of sulphur, and at the temperature of 40° became a crystalline mass, in which the relative proportions of the phosphorus and sulphur appeared to be 8 and 4. This, therefore, was probably a biposphuret of sulphur ($2p + s$), or a compound of

Phosphorus	2	32	66.7
Sulphur	1	16	33.3
<hr/>		<hr/>	<hr/>
Biphosphuret of sulphur	1	48	100.0

This purified compound did not act upon water at common temperatures, nor rapidly even at its boiling-point; hence, Mr. Faraday infers that the rapid action of the compound formed by heat in a tube when in contact with water, results from some combination of oxygen and phosphorus. When the liquid sesquichloride of phosphorus is acted on by sulphuretted hydrogen, hydrochloric acid is evolved, and a yellow substance produced which is a sesquisulphuret of phosphorus. ($p + 1\frac{1}{2}s$.)
—SERULLAS.

§ X. SELENIUM.

THIS rare and singular substance was discovered in 1818 by Professor Berzelius, during an examination of certain substances found in the sulphuric acid manufactured at Gripsholm, in Sweden. (*Ann. de Chim. et Phys.*, ix. 160.) The sulphur used in these works is procured from the iron pyrites of Fahlun, and the acid obtained from it deposits a red matter, which was supposed to contain tellurium, but the peculiarities of which were traced to a distinct and previously unknown substance, to which its discoverer gave the name of *Selenium*, from *Σελήνη*, the moon, in consequence of its having at first been mistaken for the metal Tellurium.

Some difference of opinion exists as to the place which selenium should occupy in chemical arrangements. Berzelius includes it among the metals; but as it is a non-conductor of electricity, and a most imperfect conductor of heat, and as, in other respects, it bears much analogy to sulphur, it is generally placed among the non-metallic combustibles.

Stromeyer and Rose have detected it in several metallic ores from the Hartz mines, and amongst some of the volcanic products of the Lipari islands; and it exists in some of the sulphurets of lead of Fahlun, and in the pyrites of the isle of Anglesey.

Selenium is most readily obtained by the decomposition of *selenic acid*, which may be effected by adding hydrochloric acid to its solution in water, and immersing a plate of zinc in the mixture: a gray or reddish-brown flocculent precipitate of selenium is then deposited. Berzelius, in his *Lehrbuch de Chemie*, has detailed the circuitous process by which he separated selenium from the red sediment of the Gripsholm sulphuric

acid (see also *Ann. of Phil.*, xiv. 403); and M. Lewenau has described some important improvements in the modes of obtaining it in a pure state. (*Ann. of Phil.*, N. S., viii. 104.)

To extract selenium from the native sulphuret, Magnus proposes to mix it with eight times its weight of peroxide of manganese, and to expose the mixture to a low red heat in a glass retort, the beak of which dips into water. The sulphur, oxidized at the expense of the manganese, escapes in the form of sulphurous acid, while the selenium either sublimes as such or in the state of selenious acid: should any of the latter go over into the water it would there be reduced by the sulphurous acid. (TURNER, *Elem. of Chem.*)

Selenium, when cooled after fusion, has a reddish-brown colour, and dim metallic lustre; its fracture is of a lead-gray colour. Its specific gravity is 4.32. Specific heat = 0.0837. (REGNAULT.) Obtained from its solutions by precipitation upon zinc, it is red, but becomes black when boiled in water. A dilute solution of selenic acid mixed with sulphurous acid, and exposed to light, becomes covered with a film of reduced selenium of a gold colour. When fused, and very slowly cooled, its surface is gray and granular, without lustre: and its fracture dull, like that of metallic cobalt. It is brittle, soft, and easily reduced to powder. Under certain circumstances, it assumes a prismatic crystalline texture, but not very distinct. In thin layers it is transparent, transmitting red rays; it is softened by heat, becoming semifluid at 212° , and perfectly fusing at a temperature somewhat higher; it remains for some time soft on cooling, and may be drawn out into filaments like sealing-wax, which are of a gray metallic lustre by reflected light, but by transmitted light of a clear ruby-red. Heated in a tube or small retort nearly to redness, or about 650° , it boils, and is converted into a yellow vapour of a deeper colour than chlorine, which condenses into black drops that run together like quicksilver. Heated in the open air it rises in vapour, which may be condensed into a red powder. It is characterized by tinging the flame of the blowpipe of a light blue colour, and by exhaling, when strongly heated, a peculiar and highly diffusible odour of decayed horseradish.

SELENIUM AND OXYGEN.—These bodies appear to unite in three proportions, forming an oxide and two acids.

SELENIOUS OXIDE; OXIDE OF SELENIUM ($Se + O$), is formed by heating selenium in a limited quantity of atmospheric air, and washing the product to separate a portion of acid which is at the same time formed. The characters of this compound have not been accurately examined, nor has its composition been ascertained: it is sparingly soluble in water, and passed through alkaline solutions, imparts to them its peculiar odour, but is not absorbed: it does not redden litmus. It appears to be the cause of the peculiar odour emitted during the oxidation of selenium. It probably consists of

Selenium . . .	1	40	88.3
Oxygen . . .	1	8	16.7
	<hr/>	<hr/>	<hr/>
	1	48	100.0

SELENIOUS ACID. ($Se + 2O$) or Se' .—When a current of oxygen gas is passed over selenium, heated to its boiling-point, it burns with a pale bluish-green flame, and this acid sublimes and condenses in long brilliant prismatic crystals, provided the vessel into which it is received is cold and capacious; otherwise, the sublimate is semifused and semitransparent: this is dry selenious acid: it loses its transparency by exposure to air, and rapidly absorbs water. Exposed to heat, the water separates again before the acid rises in vapour. Selenious acid may also be obtained by digesting selenium in nitric or nitrohydrochloric acid till entirely dissolved, and then evaporating to dryness. Its taste is sour and hot; its odour, when sublimed, acid, but not like that of the oxide. It is very soluble in warm water, and the solution furnishes crystals of hydrated acid. It also dissolves in alcohol, and the solution furnishes, on distillation, a liquid of an ethereal odour. If this alcoholic solution be mixed with sulphuric acid, and then distilled, the product has an odour so insupportable, that Berzelius was unable to proceed in its examination.

The selenious acid and its salts may be decomposed by mixture with solution of sulphite of ammonia and the addition of an acid. Sulphurous acid is liberated, and the selenium is slowly reduced, the solution first acquiring a yellow colour, and in the course of some hours depositing red flocculi of selenium: this effect is accelerated by a boiling heat. This acid forms precipitates in the solutions of silver and of lead; its neutral salts with alkaline bases convert vegetable blues to green, and redden turmeric. It combines also in two and four proportionals with certain bases, so that it forms *selenites*, *biselenites*, and *quadriselenites*. It forms very few subsalts.

The proportion of oxygen in this acid is, to that contained in the bases to which it unites to form neutral salts, as two to one; so that it may be considered as a compound of

						Berzelius.

SELENIC ACID. ($Se + 3O$) or Se' .—This acid was first described by MM. Mitscherlich and Nitzsch. (*Ann. de Chim. et Phys.*, vol. xxxvi., p. 100.) It is obtained by fusing selenium, or selenious acid, or any of its salts, or a metallic seleniuret, with nitrate of potassa or of soda: seleniuret of lead, as the most common ore containing it, has generally been used: it is to be digested in hydrochloric acid, to separate carbonates, and the residue mixed with its weight of nitrate of soda, and gradually thrown into a red-hot crucible; the fused mass is then well washed in hot water, which dissolves the alkaline seleniate and the nitrate: this solution, quickly boiled down, deposits seleniate of soda, and this being separated, the nitrate crystallizes on cooling; the mother-liquor again boiled deposits more of the seleniate, and in this way the salts may be separated; for the seleniate, like sulphate of soda, is more soluble in water at about 90° than at 212° . The seleniate of soda thus obtained is not quite pure; if it be mixed with hydrochlorate of ammonia and heated,

nitrogen and water are evolved, selenium sublimes, and chloride of sodium is formed: the selenium is now pure, and may be converted by nitric or nitrohydrochloric acid into selenious acid, neutralized with soda, and this converted into seleniate by fusion with nitrate of soda, solution, and crystallization, as before. The solution of this pure seleniate may now be decomposed by nitrate of lead; the insoluble seleniate of lead is well washed and diffused through water, into which a current of sulphuretted hydrogen is passed to precipitate the lead: the liquid is boiled, to evaporate excess of sulphuretted hydrogen, and is now dilute selenic acid. Its purity, as respects fixed bodies, is determined by its perfect volatility; if sulphuric acid be present, it may be ascertained by boiling a portion with hydrochloric acid, which produces selenious acid, and then testing by chloride of barium.

Selenic acid is a colourless liquid, which may be heated to about 536° without decomposition; it is partially changed at higher temperatures; and at 554° , is rapidly resolved into selenious acid and oxygen. When concentrated, by exposure to a temperature of about 329° , it acquires a specific gravity of 2.524; at 513° , it is 2.6: it may be rendered somewhat denser by evaporation at higher temperatures; but in that case a portion of selenious acid is formed in it; and it is impossible to expel the whole of its water without decomposition: it is unknown in its anhydrous state.

Selenic acid has a strong attraction for water, and evolves much heat when mixed with it; sulphuretted hydrogen does not decompose it, and hence that gas may be used to decompose some of the metallic seleniates. When boiled with hydrochloric acid, selenious acid and chlorine are produced, so that the selenio-hydrochloric acid dissolves gold upon the same principle as the nitro-hydrochloric. It dissolves zinc and iron with the evolution of hydrogen; and copper, with the production of selenious acid; it also dissolves gold, but not platinum; sulphurous acid, which decomposes selenious acid, has no action on selenic acid; so that to decompose selenic acid in this way, it must first be boiled with hydrochloric acid, which converts it into selenious acid, and the sulphurous acid, or a sulphite, then effects the separation of selenium. The affinity of selenic acid for bases is little inferior to sulphuric acid, for seleniate of baryta is not completely decomposed by sulphuric acid.

From the resemblance, in crystalline form, of the seleniates to the sulphates, Mitscherlich inferred that the proportion of oxygen in selenic acid should correspond to that in sulphuric acid; that it should be to the base as three to one; and to that in the selenious acid as three to two. These views were confirmed by experiment; the selenic acid, therefore, consists of

					Mitscherlich.

Selenic acid	1	64	100.0	100.0,		

SELENIUM AND CHLORINE.—When chlorine is passed over selenium, it is absorbed with the production of heat, and a brown liquid *chloride of selenium* ($Se + 2C$), results, not very volatile, heavier than water, and

gradually resolved by the action of water into hydrochloric and selenious acids.

Exposed to excess of chlorine, this deutochloride absorbs an additional quantity, and becomes converted into a white solid *perchloride* ($se + 3c$), which volatilizes when heated, and condenses in the form of delicate crystals. It dissolves with the evolution of heat in water, producing a colourless sour solution, which probably contains muriatic and selenic acids.

SELENIUM AND BROMINE.—These substances readily combine with the evolution of heat into a reddish-brown fuming compound, having the odour of chloride of sulphur: it is converted by the action of water into hydrobromic and selenious acids. (SERULLAS, *Ann. de Ch. et Ph.*, xxxv. 349.) It is, therefore, probably a compound of 1 atom of selenium and 2 of bromine. ($se + 2b$.)

The *iodide* and *fluoride* of selenium appear not to have been examined.

SELENIUM AND HYDROGEN; SELENIURETTED HYDROGEN; HYDROSELENIC ACID. ($se + h$) or *hse*.—This gaseous compound may most easily be obtained by the action of hydrochloric acid upon seleniuret of potassium or of iron. It is colourless, and readily dissolves in water, forming a solution at first colourless, but after a time acquiring a reddish hue: the solution smells and tastes somewhat like that of sulphuretted hydrogen; it reddens litmus, and permanently tinges the skin of a reddish-brown. Nitric acid dropped into it occasions no change, and the gas does not readily escape from the water; but, when exposed to air, the solution gradually reddens, and deposits selenium. It occasions precipitates in all solutions of neutral metallic salts, which are black or dark-brown, with the exception of those from zinc, manganese, and cerium, which are flesh-coloured.

Seleniuretted hydrogen is easily decomposed by the joint action of air and water; it is absorbed by moist substances, and soon communicates to them a red colour. The selenium is thus remarkably deposited throughout the texture of organic bodies. A piece of moist paper is penetrated by the red colour. Moist wood, and even a thin piece of caoutchouc, became in the same way red throughout. It exerts a dangerous action upon the trachea and organs of respiration; it inflames the eyes, and painfully stimulates the nasal membrane, destroying for some hours the sense of smell. Berzelius states that in the first experiments which he made upon this gas, he let up into his nostrils a bubble about the size of a pea. "It deprived me so completely of the sense of smell, that I could apply a bottle of concentrated ammonia to my nose without perceiving any odour. After five or six hours I began to recover the sense of smell, but a severe catarrh remained for about fifteen days." On another occasion, a little of the gas accidentally escaped; it produced a sharp sensation in the nose, red eyes, and a dry and painful cough, at length succeeded by expectoration tasting like the vapour from a boiling solution of corrosive sublimate. "These symptoms were removed by a blister to my chest. The quantity of seleniuretted hydrogen gas which on each of those occasions entered into my organs of

respiration, was much smaller than would have been required of any other inorganic substance whatever to produce similar effects." (*Ann. of Phil.*, xiv. 101.) Dr. Prout, in his *Bridgewater Treatise*, quotes the above passage, to show how small a quantity of foreign matter may, when diffused in the atmosphere, produce powerful effects upon the human system, and suggests the possibility of some such cause, as the origin of influenza, and some other epidemic disorders.

The specific gravity of seleniuretted hydrogen has not been ascertained, but from its analysis (BERZELIUS, *Ann. de Ch. et Ph.*, ix. 335), it appears to consist of

				Berzelius.

SELENIUM AND NITROGEN have no mutual action, nor does selenium absorb ammonia; but when seleniuret of calcium and hydrochlorate of ammonia are mixed and distilled, a red fluid is obtained, of an hepatic odour, and decomposed by exposure to air, exhaling ammonia, and leaving selenium.

SELENIUM AND SULPHUR; SULPHURET OF SELENIUM.—Sulphur and selenium may be mixed by fusion in all proportions. An addition of about one per cent. only of sulphur renders selenium more red, fusible, and transparent when cold. A true *sulphuret of selenium* may be obtained by passing sulphuretted hydrogen into a solution of selenious acid: the fluid becomes turbid, and acquires a fine yellow colour, but the precipitate is long in separating, unless a little hydrochloric acid be added: when warmed, it acquires a red colour and viscid texture, and may be distilled, without decomposition, at high temperatures. It is slowly acted upon by nitric acid, but nitro-hydrochloric acid easily decomposes it; it is soluble in the caustic fixed alkalis, and in their hydro-sulphurets, forming yellow solutions, from which acids precipitate it. Burned in the air, it at first exhales a sulphurous odour, but afterwards the smell of horseradish prevails. It is a *bisulphuret of selenium* ($se + 2s$), for it consists, according to Berzelius, of

SELENIUM AND PHOSPHORUS; PHOSPHURET OF SELENIUM.—Dropped into melted phosphorus, selenium forms a red compound, apparently soluble in all proportions in the fused phosphorus. When phosphorus is saturated with selenium, an easily-fusible compound results, which, on cooling, acquires a brown lustre and vitreous fracture. When this *phosphuret of selenium* is digested in water, a small portion of the phosphorus is oxidized, and the water acquires the odour of seleniuretted hydrogen, and deposits selenium when exposed to the air. The compound is dissolved when boiled in caustic potassa, and the solution contains phosphate and hydroseleniuret of potassa. (BERZELIUS, *Ann. de Ch. et Ph.*, ix. 238.)

§ XI. CARBON.

THE purest form of this elementary substance is the *diamond*, a mineral body first discovered in Asia, in the provinces of Golconda and Visapour, in Bengal, and in the island of Borneo. About the year 1720, diamonds were first found in the district of Serra Dofrio, in Brazil, and from this locality the European market is now chiefly supplied. They occur in detached crystals in alluvial soil; though it appears probable, from a specimen described by Mr. Heuland (*Geol. Trans.*, 2nd series, i. 419), that in Brazil the real matrix is an iron-stone which forms beds resting on primary chlorite slate. According to Mr. Voysey, the diamonds of the Nalla Malla Mountains, in Hindostan, are found in a species of pudding-stone or breccia, composed of fragments of jasper, quartz, and calcedony. (*Phil Mag.*, 2nd series, i. 147.) The primitive form of the diamond is the regular octoëdron, each triangular facet of which is sometimes replaced by six secondary triangles, bounded by curved lines; so that the crystal becomes spheroidal, and presents forty-eight facets. Diamonds, with twelve and twenty-four facets, are not uncommon. (JAMESON'S *Mineralogy*, 2nd edit., vol. i. p. 1.) The diamond has been found nearly of all colours: those which are colourless are most esteemed; then those of a decided red, blue, or green tint. Black diamonds are extremely rare. Those which are slightly brown, or tinged only with other colours, are least valuable.

The fracture of the diamond is foliated, its laminae being parallel to the sides of a regular octoëdron. It is somewhat brittle but very hard; its specific gravity varies from 3.4 to 3.6, it is most commonly 3.52. It is a non-conductor of electricity, frequently phosphorescent (p. 217), and has a very high refractive power in regard to light, as compared with its density (p. 192). It is not acted upon by any acid or alkali.

The art of cutting and polishing diamonds, though probably of remote antiquity in Asia, was first introduced into Europe in 1456, by Louis Berghen, of Bruges, who accidentally discovered, that, by rubbing two diamonds together, a new facet was produced. The particular process of forming the rough gems into *brilliant*s and *rose diamonds* has been described at length by Jeffries. (*On Diamonds and Pearls*, 3rd edit., London, 1800.) By either of these processes, but especially by the former, so much is cut away, that the weight of the polished gem does not exceed half that of the rough stone; so that the value of a brilliant-cut diamond is esteemed equal to that of a similar rough diamond of twice the weight, exclusive of the cost of workmanship. The weight, and therefore the value of diamonds is estimated in *carats*, 150 of which are about equal to one ounce troy, or 480 grains. They are divided into halves, quarters, or carat grains, eighth, sixteenth, and thirty-second parts.

The difference of value between one diamond and another of equal merit, is, generally speaking, as the squares of their respective weights: thus, the value of three diamonds, of one, two, and three carats' weight respectively, is as one, four, and nine. The average price of rough

diamonds is estimated by Jeffries at 2*l.* per carat; and, consequently, when wrought, the cost of the first carat, exclusive of workmanship, will be 8*l.*, which is the value of a rough diamond of two carats.

		£.
A wrought diamond of 3 carats is worth		72
" 4 ditto		126
" 5 ditto		200
" 10 ditto		800
" 20 ditto		3,200
" 30 ditto		7,200
" 40 ditto		12,800
" 50 ditto		20,000
" 60 ditto		28,800
" 100 ditto		80,000

This mode of valuation, however, only applies to small diamonds, in consequence of the difficulty of finding purchasers for the larger ones.

The largest known diamond is probably that mentioned by Tavernier, in the possession of the Great Mogul: its size is about that of half a hen's egg; it is cut in the rose form, and when rough, is said to have weighed 900 carats: it was found in Golconda about the year 1550. Among the crown-jewels of Russia is a diamond weighing 195 carats: it is the size of a small pigeon's egg, and was formerly the eye of a Brahminical idol, whence it was purloined by a French soldier; it passed through several hands, and was ultimately purchased by the Empress Catherine, for the sum of 90,000*l.* in ready money, and an annuity of 4000*l.* Perhaps the most perfect and beautiful diamond hitherto found, is a brilliant brought from India by an English gentleman of the name of Pitt, who sold it to the Regent Duke of Orléans, by whom it was placed among the crown jewels of France: it weighs rather more than 136 carats, and was purchased for 100,000*l.* In the year 1828, a collection of diamonds of extraordinary size and beauty was in the possession of Messrs. Rundell, Bridge, and Co., of London: the suite consisted of eight, of various shapes and sizes, the smallest weighing 55 grains, and the largest 151 grains: with one exception they were all brilliant cut.

The principal use of the diamond is in jewellery, but it is also importantly applicable in some of the arts; in consequence of its extreme hardness it is employed for the pivot-holes in delicate watch and clock-work, and it has been used to form the holes through which extremely fine wires are drawn: it also furnishes the only convenient tool for cutting glass; for this purpose the edge of one of the small curvilinear crystals is used, for the edges of the crystals formed by flat plates only scratch, without producing that peculiar fissure by which the glass can be smoothly split. Microscopic lenses have also been formed of diamond.

CHARCOAL.—This is another well-known form of *carbon*: it is obtained in abundance by the destructive distillation of various organic products, and its characters and properties vary with its source. It may be prepared by heating pieces of wood in a close vessel, or in a crucible covered with sand, to redness, and keeping them in that state for about an hour, or till all volatile matters are expelled. They are thus converted into a black brittle porous substance, which appears to be essentially the same, from whatever kind of wood it has been procured.

Common charcoal, employed as fuel, is usually made of oak, chestnut, elm, beech, or ash wood, the white and resinous woods being seldom used. Young wood affords a better charcoal than large timber, which is also too valuable to be thus employed. The billets are formed into a conical pile, which, being covered with earth or clay, is suffered to burn with a limited access of atmospheric air, by which its complete combustion, or reduction to ashes, is prevented. (See URE's *Dict. of Arts*, Art. CHARCOAL.)

Another, and a more perfect mode of preparing charcoal, consists in submitting the wood to a red heat in a kind of distillatory apparatus consisting of cast-iron cylinders, from which issue one or more tubes for the escape of gaseous matters and vapours. The makers of gunpowder particularly prefer this process. (A plate of this apparatus is given in PARKES *Chemical Essays*.)

The quantity of charcoal obtained from different kinds of wood is liable to much variation. The following table drawn up from the experiments of Allen and Pepys (*Phil. Trans.*, 1807), and of Griffiths (*Quar. Jour.*, xvi. 264), shows the produce of charcoal from 1000 parts of several varieties of dense and light woods.

Ebony	305	Box	202
Botany Bay-wood	281	Fir	181
Brazil-wood	260	Lignum-vitæ	175
Eveas-wood	225	Oak	174
King-wood	220	Mahogany	157
Tulip-wood	208	Beech	150
Satin-wood	207		

Charcoal is a black, insoluble, inodorous, insipid, brittle, substance; an excellent conductor of electricity, but a bad conductor of heat; unchanged by the combined action of air and moisture at common temperatures, and easily combustible in oxygen gas. Its specific heat, as estimated by Regnault, is 0.24111; the average, as given by Dulong and Petit, is 0.25. When pure it is perfectly infusible at all known temperatures; in the cases in which it was supposed to have been fused, some impurities apparently have existed in the charcoal employed; upon this subject a series of experiments have been published by Silliman (*Quarterly Journ.*, xvi. 157). Under common circumstances of ignition it does not appear to volatilize, but from the experiments of Leplay and Laurent (*Ann. C. et P.*, lxxv. 417), it seems not improbable that in the process of steel-making the penetration of iron by carbon may be partly due to its volatility. It is capable of destroying the smell and taste of a variety of vegetable and animal substances, and of abstracting certain substances dissolved in fluids. (LOWITZ, CRELL's *Annals*, ii. 165.) The use of charring piles; of throwing charcoal into putrid water; of wrapping it in clothes that have acquired a bad smell; of adding it to port wine, with a view of making it tawny, depends upon the above properties. M. Bussy has published some interesting observations on the discolouring power of charcoal, in the *Journal de Pharmacie* for June, 1822, of which an abstract will be found in the *Quarterly Journal*, xiii. 406. It appears from his experiments, that certain physical conditions are requisite for the manifestation of this property, especially porosity and minute division,

and that it is not possessed by any hard and brilliant charcoal even when finely powdered. Upon this principle, he accounts for the superior efficacy of the charcoal obtained by burning animal substances, over that of vegetables, in the destruction of colour. According to Payen, animal charcoal, boiled with lime-water, deprives it entirely of lime, an effect not produced by lamp-black or vegetable charcoal. (*Quarterly Journal*, xv. 384.) Well-burned charcoal shaken with water contaminated by sulphuretted hydrogen, entirely deprives it of that gas, so that when filtered it is not only inodorous, but is not discoloured by solution of lead.

Newly-made charcoal has the property of absorbing certain quantities of the different gases. Upon this subject the experiments of M. Theodore de Saussure are the most recent. (THOMSON'S *Annals*, vol. vi.) The charcoal was heated red-hot, then suffered to cool under mercury, and introduced into the gas. The following are the volumes of different gases absorbed by a volume of charcoal = 1.

Ammonia	90	Bicarburetted hydrogen	35
Hydrochloric acid	85	Carbonic oxide	9.42
Sulphurous acid	65	Oxygen	9.25
Sulphuretted hydrogen	55	Nitrogen	7.5
Nitrous oxide	40	Carburetted hydrogen	5
Carbonic acid	35	Hydrogen	1.75

The absorption was always at its maximum at the end of twenty-four hours, not being increased by retaining the charcoal in the gas. When charcoal, already saturated with any one gas, is put into another, it gives out a portion of the gas already absorbed, and takes up a portion of the new gas. It would also appear that this absorptive quality partly depends upon the mechanical texture of the charcoal, and consequently will vary in the different woods; for, by exposing the charcoal of different woods to air, Allen and Pepys found that they increased very differently in weight.

By a week's exposure, charcoal from

Lignum-vitæ gained	9.6 per cent.	Beech	16.3 per cent.
Fir	13.0 "	Oak	16.5 "
Box	14.0 "	Mahogany	18.0 "

The matter absorbed in these cases consisted principally of aqueous vapour, which is very greedily imbibed by newly-made charcoal.

According to Vogel, when recently-ignited charcoal, which has been cooled under mercury, is put into a jar of atmospheric air, it absorbs the oxygen of the air to a much greater extent than the nitrogen. (SCHWEIGER'S *Journal*, iv.) A piece of well-burned charcoal cooled under mercury and then introduced into a mixture of oxygen and sulphuretted hydrogen gases rapidly absorbed them, and then became ignited and caused explosion. (A. TAYLOR.)

WOOD CHARCOAL generally contains about one-fiftieth of its weight of alkaline and earthy salts, which remain in the form of *ash*, after its combustion, but the quantity and quality of this ash vary considerably in different trees and plants.

ANIMAL CHARCOAL, obtained by the carbonization of animal substances, such as muscle, horn, or hoof, resembles the former in its general characters, but instead of retaining the form of the matter from which it is produced, as is the case with the generality of vegetable charcoal, it appears as if it had undergone fusion, and often has a peculiar lustre and sponginess. The residuary charcoal, obtained by the distillation of bone, is called *ivory-black* in commerce, and is very impure, being mixed with the phosphate of lime and other salts contained in the earthy part of the bone, so that for many purposes it requires to be freed from its earthy salts by digesting it in dilute hydrochloric acid, and then washing and drying it; but by this process its discolouring power is greatly impaired. Some of the peculiarities of animal charcoal as regards the destruction of odours and colour have already been mentioned, and have been referred to its peculiar texture, rather than to any peculiarity of composition, charcoal being essentially the same, under all its various forms. When vegetable matter, for instance, mixed with earthy substances are charred, they yield a product the properties of which resemble those of animal charcoal: thus a mixture of 100 parts of thin pipe-clay, 20 of tar, and 500 of powdered coal dried and calcined, gave a charcoal of great decolourizing power. Of the different kinds of charcoal used for decolouration, bone charcoal, or ivory black, is most feeble, although it is far superior to the best wood charcoal. The following table shows the efficiency of several varieties of these charcoals compared with ivory-black. Column I. represents 1 gramme (or 15·4 grains) of the different kinds of charcoal experimented on. Column II. shows the quantity of test indigo liquor (in grammes) decoloured by each gramme of the respective charcoals; this indigo liquor contained one-thousandth of indigo, so that each gramme of the decoloured liquor represents a thousandth of a gramme of indigo absorbed by the charcoal. Column III. shows the relative decolouration of a solution of 1 part of raw sugar in 20 of water, also in grammes. Column IV. shows the relative decolouration of the indigo, and Column V. that of the brown syrup, in reference to the effect of ivory-black.

I.	II.	III.	IV.	V.
1. Common bone charcoal, or ivory-black	32	9	1·00	1·00
2. Oil charred with phosphate of lime	64	17	2·00	1·90

9. Starch calcined with carbonate of potassa	340	80	10·60	8·80
10. Albumen or gelatin calcined with carbonate of } potassa	1115	140	35·00	15·50
11. Blood charred with phosphate of lime	380	90	12·00	10·00
12. Blood charred with carbonate of lime	570	100	18·00	11·00
13. Blood charred with carbonate of potassa	1600	180	50·00	20·00

LAMP-BLACK is prepared principally by the combustion of refuse and residuary resin, left by the distillation of turpentine. It is burned in a furnace, so constructed that the dense smoke arising from it may pass into

chambers hung with old sacking, where the *soot* is deposited, and from time to time swept off, and sold without any further preparation. (AIKIN'S *Dictionary*, Art. *Charcoal*. DUMAS, *Chim. App. aux Arts*.) When lamp-black has been heated red-hot, it may be regarded as a very pure form of charcoal, for it burns entirely away, and leaves no residuary ash: when, however, the products of its combustion are closely examined, it is found to yield traces of water, and therefore probably contains hydrogen in chemical combination. A substance analogous to lamp-black is obtained by passing the vapour of certain oils, and of hydrocarbonous compounds, through red-hot tubes; at that high temperature they are more or less perfectly decomposed, and let fall a quantity of very impalpable charcoal, in which, however, as in lamp-black, traces of hydrogen may be detected. One of the principal uses of lamp-black is in the manufacture of printer's-ink. For this purpose it has lately been obtained by the combustion of purified coal-tar. (URE'S *Dict. of Arts*, Art. *Black*.)

COAL-GAS CHARCOAL.—A very singular form of charcoal is occasionally deposited in coal-gas retorts, and in the tubes connected with them, resulting from the decomposition of the first products of the distillation of coal. It has a gray colour, and often exhibits a laminated texture; its streak is black, and it breaks with an earthy fracture: its specific gravity is about 1·8. It sometimes happens that the gas escapes through some crack in the retort, in which case a peculiar carbonaceous deposit forms upon the surrounding brick-work, of a stalactitic character, an iron-gray colour, and considerable lustre; it does not easily burn, nor does it soil the fingers; and some specimens, as far as mere appearance goes, might be considered as metallic. Its specific gravity is about 1·75. Some years ago, Mr. Charles Macintosh, of Glasgow, made steel by passing coal-gas over ignited iron, placed in an air-tight iron chest: in this process much carbon was deposited in various states, but some of it assumed the remarkable form of capillary filaments, and tufts of a metallic lustre; they were very difficult of combustion, but when deflagrated with nitre yielded no trace of iron, and were apparently pure carbon. All these forms of carbon were conductors of electricity. (COLQUHOUN, *Ann. of Phil.*, N.S., xii. 50.)

PLUMBAGO. GRAPHITE. BLACK LEAD.—This substance must be considered as one of the forms of carbon. It is well known in the manufacture of pencils, for which purpose it is almost exclusively obtained from the mine of Borrowdale, at the west end of Derwent Lake, in Cumberland, where it was first wrought during the reign of Elizabeth. In a less pure state it is not an uncommon mineral, occurring in detached masses generally in primitive rocks. It is of an iron-gray colour, metallic lustre, and soft and greasy to the touch: its specific gravity varies from 1·9 to 2·3; it occasionally occurs crystallized in hexangular plates; it conducts electricity, is infusible, and very difficult of combustion: when burned in a stream of oxygen gas, it leaves a small quantity of yellow ash, composed chiefly of oxide of iron, but varying in quantity in different specimens. According to Vanuxen (SILLIMAN'S *Jour.*, x. 105), the following are the components of three varieties of this mineral; the two first are the pure

and impure varieties from Borrowdale, and the third a pure specimen from Bustletown, Pennsylvania.

	1.	2.	3.
Carbon	88.37	61.27	95.4
Water	1.23	5.33	0.6
Silica	5.10	10.10	2.6
Alumina	1.00	3.20	0.0
Oxides of iron and manganese .	3.60	20.00	1.4
	<hr/> 99.30	<hr/> 99.90	<hr/> 100.0

Schrader analyzed the ashes remaining after the combustion of 200 grains of English and 200 grains of Spanish plumbago, with the following results. (*Ann. of Phil.*, i. 294.)

	Borrowdale.	Spanish.
Protoxide of iron	11.6	14.2
Silica	7.0	3.0
Alumina	4.6	2.4
Oxide of copper	0.0	1.0
Titanic acid	6.3	3.1
	<hr/> 29.5	<hr/> 23.7

It seems, probable, therefore, that in plumbago the oxide of iron is in combination with titanic acid and silica, and not with the carbon so as to constitute a *carburet of iron*. Some specimens, indeed, as those from Barreros in Brazil, scarcely contain a trace of iron.

ANTHRACITE. MINERAL CHARCOAL. GLANCE-COAL.—The *culm* of Wales, and the *Kilkenny-coal* of Ireland, are species of this mineral. It much resembles common coal in appearance, but is difficult of combustion, and burns without flame, smell, or smoke, and leaves very little ash. Its specific gravity is about 1.4.

COKE is the carbonaceous residue of the distillation of pit-coal; it has a porous texture, and more or less lustre, frequently appearing metallic; in small fragments it is very difficult of combustion in the flame of a candle, but when employed in large masses as fuel, it produces an intense and steady heat. It varies extremely in purity, but when carefully prepared from the purest varieties of coal, it leaves very little residue after combustion.

Such are the principal varieties of carbon: the diamond appears to be this element in its pure form, for it burns away without residue, and affords no appreciable traces of any foreign matter: the other forms of carbon, on the contrary, yield indications of extraneous substances, such as hydrogen, or metals, or their oxides. They are all infusible, and the porous varieties are very bad conductors of heat: with the exception of the diamond, they conduct electricity, but some of them more perfectly than others, and plumbago and very dense and well-burned wood-charcoal almost rival some of the metals in this respect; this circumstance, and the strong lustre of some of the species of charcoal, seem almost to justify Döbereiner in placing it among the metals under the name of *Carbonium*.

CARBON AND OXYGEN.—Though these substances possess for each other a very powerful affinity, they do not combine at common tempera-

tures: to this remark, however, there are, perhaps, some exceptions, and it appears that certain forms of carbon may exist, which produce carbonic acid whenever they come into contact with oxygen; these are, probably, peculiar to organic combinations.

There are three definite compounds of carbon and oxygen; namely, the *carbonic oxide*, *carbonic acid*, and *oxalic acid*; the oxalic acid is exclusively derived from organic products, and, in all its chemical relations, is so connected with the *vegetable acids*, that I shall refer it and its combinations to that class of bodies: Döbereiner has termed it the *carbonous acid*; but, as Berzelius observes, there is not that analogy between the oxalic and carbonic acids that exists in reference to the sulphurous, and phosphorous, and sulphuric, and phosphoric acids, and which would justify such nomenclature. L. Gmelin includes *croconic acid* among the combinations of carbon and oxygen: it is produced during the action of charcoal upon carbonate of potassa at high temperatures, (see Potassium,) and consists according to Gmelin of 5 atoms of carbon and 4 of oxygen, if supposed anhydrous. The *mellitic acid* in its anhydrous state is also placed by Liebig and Wöhler among the acids of carbon, containing 4 atoms of carbon and 5 of oxygen. We shall here limit ourselves to the history of carbonic oxide and carbonic acid; but assuming the existence of anhydrous oxalic, croconic, and mellitic acids, we have the following formulæ of the combinations of carbon and oxygen:—

CARBONIC OXIDE. GASEOUS OXIDE OF CARBON. ($car + o$) CO or C̄. This gas, which was discovered by Dr. Priestley (*Obs. on Air*, i. 298), is usually obtained by subjecting *carbonic acid* to the action of substances which abstract a portion of its oxygen. Upon this principle it is produced by heating in an iron retort, a mixture of chalk and charcoal; or of equal weights of chalk and iron or zinc filings. It is also obtained by heating a mixture of equal parts of oxide of zinc and charcoal; but the mixture that affords it most pure is equal parts of carbonate of baryta and clean iron-filings; these should be introduced into a small earthen retort, so as nearly to fill it, and exposed to a red heat: the first portion of gas being rejected as mixed with the air of the retort, it may afterwards be collected quite pure: it should, however, be well washed with lime-water, and may afterwards be preserved over water. Carbonic oxide may also be obtained by gently heating oxalic acid with five or six times its weight of sulphuric acid; the mixture effervesces in consequence of the evolution of equal volumes of carbonic oxide and carbonic acid gas; the latter may be abstracted by a caustic alkaline solution, and pure carbonic oxide gas remains. (DUMAS, *Edinburgh Journal of Science*, vi. 350.) In this case the evolution of carbonic oxide is caused by the abstraction of water from oxalic acid which contains in its anhydrous state the elements of 1 atom of carbonic oxide and 1 atom of carbonic acid, but these can only exist

as oxalic acid when in union with water, or with a base, anhydrous oxalic acid not having been isolated. It not unfrequently happens that carbonic oxide is formed by the combustion of carbon when the supply of oxygen is inadequate to the production of carbonic acid: hence the lambent blue flame which sometimes plays upon a coke or charcoal fire, or is seen to issue from certain furnaces.

The nature of carbonic oxide was first made known by Mr. Cruickshank, of Woolwich, in 1802 (NICHOLSON'S 4to. *Journal*, v.); and about the same time it was examined by Clement and Desormes. (*Ann. de Chim.*, xxxix. 26.)

The specific gravity of this gas compared to hydrogen is as 14 to 1; and to atmospheric air as 0.972 to 1000; 100 cubical inches weighing 30.2 grains. (At the temperature of 32° 100 cubic inches weigh 31.8790 grains. THOMSON.) It is fatal to animals, and produces giddiness and fainting when respired mixed with atmospheric air. (*Phil. Mag.*, xliii. 367.) When breathed pure it almost immediately induces profound coma. It extinguishes flame, and burns with a peculiar blue light, when mixed with, or exposed to, atmospheric air. Sir H. Davy found that the temperature of an iron wire heated to dull redness, was sufficient to inflame it. It has no taste and little odour, it does not affect vegetable colours, occasions no precipitate in lime water, and is very sparingly absorbed by water which has been deprived of air. When burned under a dry bell-glass of air or oxygen, no moisture whatever is deposited, showing that it contains no hydrogen.

Carbonic oxide suffers no change by being passed and repassed through a red-hot porcelain tube; nor is it decomposed at high temperatures by phosphorus, sulphur, nor even, according to the experiments of Saussure, by hydrogen (*Journal de Physique*, lv.), though it is stated, upon other authorities, that at high temperatures hydrogen does decompose it. When one volume of carbonic oxide is detonated with one of nitrous oxide, there result one volume of carbonic acid and one of nitrogen. (HENRY, *Ann. of Phil.*, N. S., viii. 299.) On this principle is founded a method of ascertaining the purity of nitrous oxide, it being implied, that that gas is free from nitric oxide. Let a given volume, say 100 measures, be exploded with slight excess of carbonic oxide,—if the nitrous oxide be pure, 100 measures of carbonic acid should be produced, and whatever is short of that proportion may be ascribed to impurity. None of the metals exert any action upon this gas, except potassium and sodium, which, at a red heat, burn in it by abstracting its oxygen, and carbon is deposited. Dr. Henry found, that when a mixture of carbonic oxide with more than half its volume of oxygen is exposed over mercury in contact with spongy platinum, to a temperature between 300° and 310° , it begins to be converted into carbonic acid, and, at a heat a few degrees higher, is quickly acidified. At common temperatures these mixtures are very slowly acted on. When carbonic oxide is added in an equal volume to a mixture of hydrogen and oxygen gases in explosive proportions, it prevents spongy platinum from causing detonation; but the gases slowly act on each other, and form water and carbonic acid. The platinum occasions mixtures containing less carbonic oxide to explode. (*Phil. Trans.*, 1824, p. 271.)

The composition of carbonic oxide is determined by the result of its combustion with oxygen, with which it forms carbonic acid. In this case, when *two* volumes of carbonic oxide and *one* of oxygen are acted on by the electric spark, detonation ensues, and *two* volumes of carbonic acid are produced: hence it follows, that carbonic oxide contains half as much oxygen, and *the same* quantity of carbon, as carbonic acid; if, therefore, we assume, that it is constituted of one volume of gaseous carbon, and one volume of oxygen, (the specific gravity of the vapour of carbon being 0·84, and the specific gravity of oxygen being 1·11,) the specific gravity of carbonic oxide should be $\frac{0\cdot84+1\cdot11}{2}=0\cdot97$,

which agrees with the experimental result: or

	Grains.
50 cubic inches of the vapour of carbon	= 12·7
50 " oxygen . . .	= 17·3
100 " carbonic oxide . .	= 30·

Assuming carbonic oxide to be a *protoxide of carbon*, the number 6 may be assumed as the equivalent of carbon, and carbonic oxide will consist of

	Gay Lussac.
Carbon . . . 1 . . 6 . . 42·9 . . 43·	
Oxygen . . . 1 . . 8 . . 57·1 . . 57·	
I 14 100·0 100·	

Or, by volume, as follows:—

Carbon.	Oxygen.	=	Carbonic Oxide.	or	Carbon. 6	=	Carbonic Oxide. 14
					Oxygen. 8		

It has been above observed (p. 163), that in order to assimilate the equivalent of carbon to that deduced from its specific heat, it would require that it should be assumed as 6×2 , or 12; in that case carbonic oxide would be (*car* + 2 *o*) and carbonic acid (*car* + 4 *o*), and the majority of the carbonates would become dibasic salts. In assuming the theoretical combining volume of carbon vapour to be half that of hydrogen, and to correspond with that of oxygen, I have been guided by Mitscherlich, as explained in a note referring to the constitution of carbonic acid. I have adopted the number 6 as the equivalent of carbon, consistently with the theoretical view of Dr. Prout. Dr. Turner employs the equivalent 6·13, and Mr. Graham 6·12. Dumas has lately shown that 6 is nearer the truth.

Carbonic oxide is sometimes represented as performing the part of an elementary base; uniting, for instance, with oxygen to form carbonic and oxalic acids: with chlorine to form chlorocarbonic acid, and with amide to form oxamide; hence, in regard to *oxalic acid*, the term *oxalyde* proposed for it by Berzelius.

CARBONIC OXIDE AND CHLORINE. OXYCHLORIDE OF CARBON. CHLOROCARBONIC OR CHLOROXICARBONIC ACID. PHOSGENE GAS. (*car* + *o* + *c*.)

—This gas was obtained by Dr. J. Davy (*Phil. Trans.*, 1812, p. 144), by exposure to solar light of a mixture of equal volumes of chlorine and carbonic oxide, hence its name, from *φως*, *light*, and *γεννέω*, to *produce*. It is also formed by exposing the mixed gases to ordinary daylight, but several hours are required for the purpose. When perfectly excluded from light these gases exert no mutual affinity. In the sunshine the mixture diminishes in bulk to half its original volume, and forms a compound of a very peculiar and pungent odour, but not disagreeable when considerably diluted. It reddens litmus; is soluble in water, and resolved by it into *carbonic and hydrochloric acid gases*. Alcohol takes up 12 times its volume, and acquires a peculiar taste, and the odour of the gas. The specific gravity of chlorocarbonic acid to hydrogen is as 50 to 1, and to common air as 3·472 to 1. 100 cubical inches weigh about 106 grains: at 32°, 100 cubical inches weigh 113·85 grains. (THOMSON.)

When tin or zinc are heated in one volume of this gas, they abstract and combine with the chlorine, and evolve one volume of carbonic oxide, hence chlorocarbonic acid consists of

Or, by volume

Carbon	1	6	12
Oxygen	1	8	16
Chlorine	1	36	72
<hr/>						
Chlorocarbonic acid		1		50		100

Carbon.	Chlorine.	=	Chloro-carbonic Acid.
Oxygen.			

Chlorocarbonic acid therefore, in reference to the theory of substitutions, has been regarded as carbonic acid in which one equivalent of oxygen is replaced by one of chlorine.

CHLOROCARBONATE OF AMMONIA.—Chlorocarbonic acid condenses four volumes or two atoms of ammonia, producing a peculiar deliquescent compound of a white colour, which is resolved by the action of water into hydrochlorate and carbonate of ammonia. This salt is also decomposed by sulphuric, nitric, and hydrochloric acid, which evolve from it two volumes of hydrochloric and one volume of carbonic acid; it dissolves without effervescence in acetic acid, and sublimes unaltered, when heated in carbonic or sulphurous acid gas.

Its components are

Carbon	. 1 . . 6 . . 7·2	Chlorocarbonic acid	1 . . 50 . . 59·5
Oxygen	. 1 . . 8 . . 9·5		
Chlorine	. 1 . . 36 . . 42·8

CARBONIC ACID. FIXED AIR, AERIAL ACID. (*car* + 2 *o*) or *car'*,

or CO₂ or C̄.—This important compound was discovered by Dr. Black, in 1757, and described by him under the name of *fixed air*, in his inaugural dissertation on magnesia. It may be obtained by burning carbon, either pure charcoal or the diamond, in oxygen gas; the oxygen suffers no change of bulk, so that the composition of carbonic acid may be learned by comparing its weight with that of an equal volume of pure oxygen.

Combustion of the Diamond.—The combustibility of the diamond seems first to have occurred to Newton. In the year 1694, the Florentine Academicians verified his anticipations, and proved its destructibility by heat by means of a burning lens. The *products* of its combustion were first examined by Lavoisier in 1772, and subsequently with more precision by Guyton Morveau, in 1785. (*Ann. de Chim.*, xxxi.) In 1797, (*Phil. Trans.*,) Mr. Tennant demonstrated the important fact, that when equal weights of diamond and pure charcoal were submitted to the action of red-hot nitre, the results were in both cases the same: and, in 1807, (*Phil. Trans.*,) the combustion of the diamond in pure oxygen was found by Messrs. Allen and Pepys to be attended with precisely the same results as the combustion of pure charcoal.

When the diamond is heated in the flame of the blow-pipe it soon begins to burn, and the combustion continues as long as the temperature is sufficiently high, but it does not produce heat enough, during its combination with the oxygen of the atmosphere, to maintain its combustion. If, whilst thus burning, it be introduced into a jar of pure oxygen, the combustion continues longer, and sometimes till the whole is consumed: the best support for it, in this experiment, is a small loop of platinum wire, or a very small and thin platinum spoon, perforated with many holes; in this it may first be intensely heated by the oxygen blow-pipe, and whilst burning, carefully immersed into a bottle of pure oxygen gas containing a little lime-water: a good cork, through which the wire of the spoon passes, should secure the mouth of the bottle: it will thus go on burning brilliantly for some time, and the formation of carbonic acid be shown by the milkiness of the lime-water.

The combustion of the diamond may be more perfectly effected by placing it upon a platinum capsule in a jar of pure oxygen inverted over mercury, and throwing upon it the focus of a burning lens. Sir H. Davy, when at Florence, in 1814 (*Phil. Trans.*, 1814, p. 558), used for this purpose the lens employed in the first trials on the action of solar heat on the diamond, instituted by Cosmo III., Grand Duke of Tuscany: he found that the diamond continued to burn in the oxygen, after being withdrawn from the focus, with so brilliant a light as to be visible in the brightest sunshine, and with very intense heat.

The following is another form of apparatus which may be employed for exhibiting the results of the combustion of the diamond. It consists

of a glass globe, of the capacity of about 140 cubical inches, furnished with a cap, having a large aperture; the stop-cock, which screws into this cap, has a jet A, rising from it, nearly into the centre of the globe; this is destined to convey a small stream of hydrogen, or other inflammable gas. Two wires, c c, terminate at a very little distance from each other, just above this jet, and are intended to inflame the stream of hydrogen by electrical sparks; one of them commences from the side of the jet, the other is enclosed and insulated nearly in its whole length in a glass tube: the tube and wire pass through the upper

part of the stop-cock, and the wire terminates on the outside in a ball or ring D, at which sparks are to be taken from the machine, either directly or by a chain. On the end of the jet is fixed, by a little socket, a small capsule B, made of thick platinum-foil. This capsule is pierced full of small holes, and serves as a grate to hold the diamonds. Its distance is about three quarters of an inch from the end of the jet; and the arm, by which it is supported, is bent round, so that the stream of hydrogen shall not play against it. The stop-cock screws by its lower termination on to a small pillar, fixed on a stand, and at the side of this pillar is an aperture, by which a bladder filled with gas may be connected with the apparatus.

On using the apparatus, the diamond is to be placed in the capsule; and then the globe being screwed on to the stop-cock, the latter is to be removed from the pillar and placed on the air pump; the globe is then to be exhausted, and afterwards filled with pure oxygen; or, lest the stream of oxygen in entering should blow away the diamond, the globe may be filled with the gas first, and then, dexterously taking out the stop-cock for a short time, the diamonds may be introduced, and the stop-cock replaced. The apparatus is then to be fixed on the pillar, and a bladder of hydrogen gas attached to the aperture. Now, passing a current of sparks between the wires, a small stream of hydrogen is to be thrown

in, which inflaming, immediately heats the diamonds and capsule white-hot; the diamonds will then enter into combustion, and the hydrogen may be immediately turned off and the bladder detached. The diamonds will continue to burn, producing a strong white heat, until so far reduced in size as to be cooled too low by the platinum with which they lie in contact. When the flame of hydrogen is used to heat the diamonds, it is evident a little water will be formed in the globe, but this is of no consequence except in attempts to detect hydrogen in the diamond; the inconvenience may be obviated, if required, by using the flame of carbonic oxide. As, however, no hydrogen has at any time been detected in the diamond, it is better to use that gas as the heating agent: for then the carbonic acid, produced by the combustion, is unmixed with that from any other source, and may be collected, and its quantity ascertained.

The following method of illustrating the products of the combustion of the diamond was employed by Messrs. Allen and Pepys (*Phil. Trans.*, 1807): *a a* are mercurial gasometers, one of which is filled with pure oxygen gas. The brass tubes *b b*, properly supplied with stop-cocks, issue

from the gasometers, and are connected with the platinum tube *c c*, which passes through the small furnace *d*. *e* is a glass tube passing into the mercurio-pneumatic apparatus, by which the gas may be drawn out of the gasometers into convenient receivers. A given weight of diamond is introduced into the centre of the platinum tube, which is then heated to bright redness, and the gas passed over it, backwards and forwards, by alternately compressing the gasometers. Carbonic acid is soon formed, and it is found that the increase of weight sustained by the oxygen is equivalent to that lost by the diamond; that the oxygen undergoes no

change of bulk; and that the results are, in all respects, similar to those obtained by a similar combustion of perfectly pure charcoal.

When *charcoal* is burned in oxygen, the phenomena of the combustion very much depend upon the nature of the charcoal, which, if well burned, and of a dense wood, glows with intense heat and gradually disappears, but if of a lighter wood, and especially if covered with portions of the bark, throws off jets of brilliant sparks, and furnishes one of the most striking experiments. A small piece of the purest graphite, such as is used for pencils, may also be burned in oxygen, and its combustion much resembles that of the diamond; it should first be carefully annealed by slowly heating it to redness in the flame of a spirit lamp, then attached to a loop of fine platinum wire, heated to whiteness in the oxygen blow-pipe, and in that state introduced into the oxygen, as above directed in regard to the diamond.

Preparation, Liquifaction, and Solidification of Carbonic Acid Gas.—For all the common purposes of experiment, carbonic acid is best procured

by the action of dilute hydrochloric acid upon white marble, which, in small fragments, is introduced into the two-necked bottle *a*, and covered with water; hydrochloric acid is then slowly poured down the funnel *b*, which causes an immediate effervescence, and the gas passes through the bent tube *c*, into the inverted jar *d*. When the action ceases, it may be renewed by the addition of fresh acid, until the whole

of the marble is dissolved. When large quantities of carbonic acid are required, chalk and dilute sulphuric acid are generally resorted to, and for some particular purposes bicarbonate of soda and dilute sulphuric acid are used.

Carbonic acid may be collected over water, but must be preserved in vessels with glass stoppers, since water, at common temperature and pressure, slowly absorbs it. When required perfectly pure, the gas should be first washed by passing it through water, and then deprived of hygro-metric moisture by passing it through a long tube filled with fragments of fused chloride of calcium. Carbonic acid is a colourless gas, of a slightly sour odour, considerably heavier than atmospheric air, its specific gravity being about 1.52. Compared with hydrogen its specific gravity is as 22 to 1, and 100 cubic inches weigh 47.26 grains, (49.9780 grains at the temperature of 32°. THOMSON.)

Liquid Carbonic Acid.—At all common temperatures and pressures carbonic acid retains the gaseous state, but when duly subjected to great pressure it becomes liquid. To effect its liquifaction Mr. Faraday proceeded as follows:—A strong tube, of about one-fourth of an inch diame-

ter and eight inches long, being bent, at about two inches from its end, to an obtuse angle, and sealed at the shorter end, sulphuric acid was poured in through a small funnel, so as not to soil the larger leg, which was then loosely filled with fragments of carbonate of ammonia, and also hermetically sealed; the acid was then made to run upon the salt, and the evolved carbonic acid gradually appeared in the liquid form. The utmost precautions are here necessary to guard against explosion: such as goggles and a glass mask to preserve the face and eyes, and thick gloves for the hands: the tubes should also never be touched without great care; for sometimes, after having held the fluid safely for weeks together, they have exploded from some very slight increase of temperature. (*Phil. Trans.*, 1823.)

The liquifaction of carbonic acid is now conducted upon a large scale, especially by Mr. Addams, of Kensington, who sometimes has treasured up, in suitable reservoirs, as much as nine gallons at one time, and has even made it an article of commerce. He has been kind enough to give me the following details upon this subject:—

The apparatus he employs is of two kinds: the first, or simple mode, is dependent upon the chemical forces disengaging the carbonic acid, from the materials used under confinement, as originally suggested by Faraday; and in this, the general construction of the instruments employed is similar to those of M. Thilorier, although in respect to form, material, and structure, of the valves, there is considerable difference, being more simple in arrangement, and lighter in proportion to strength.

The second, or improved method, is partly dependent upon the chemical forces, and partly effected by mechanical compression with powerful pumps.

For either process two strong wrought-iron vessels are required, one is named the *generator*, A (fig. 255), the other the *receiver* B (fig. 256); each of these vessels is a cylinder two feet long and four inches internal diameter, having hemispherical ends, and of such strength as to bear proving to more than 4000 lbs. upon a square inch.

The generator is furnished with an axis *a*, and mounted upon a cast iron frame so as to revolve in a vertical plane *a a* (fig. 260). At one end of each vessel is screwed on a peculiar valve (fig. 257), so constructed as

to prevent leakage in the screw part, when the valve is opened. The lower, or valve part, of the central screw, to which the handle *H* is applied, is formed into a cone, which when screwed down shuts up the passage into the vessel; but when the screw is raised or turned backwards, there is a passage from the vessel and out of the side vent *s*; at the same time the upper conical shoulder of the valve comes into its seat in the plug-piece through which the valve-screw itself passes, and thus prevents escape of gas by the sides of the screw.

The *generator* is simply a hollow vessel within, but the *receiver* has a slender pipe, open at both ends, inserted into the valve-plug, and descending nearly to the bottom, as shown by *T T* (fig. 258) in the section.

The materials used in the production of liquid carbonic acid are as follows, namely, water at 100° , bicarbonate of soda in fine powder, and sulphuric acid of full commercial strength; and for a generator of the dimensions before described the proportions are, water 6.25 lbs., bicarbonate 2.75 lbs., and sulphuric acid 1.47 lbs. These proportions leave an excess of alkaline salt, which is desirable in order to prevent the action of the acid upon the metal of the generator.

To charge the generator, the valve plug is taken out, and a funnel inserted in its place; through this a part of the tepid water is introduced, then the carbonate, and afterwards the remainder of the water, and then stirred with a rod.

The acid is next put in, but to prevent its action before the valve plug is replaced, it is contained in a brass tube (fig. 259), of such diameter and length as to hold the measure of acid and also

259

pass through the orifice in the neck of the generator, and to stand erect with its open end above the saline mixture within, as shown in fig. 260. The valve-plug is now firmly screwed to the generator, and the whole inverted and turned over and over, by which the acid comes into contact with the carbonate of soda, and the mixture is completely effected. Then by allowing the generator to stand a few minutes erect, with the valve end upwards, the liquified carbonic acid, being lighter than the resulting sulphate of soda, rises, and floats as a distinct stratum. A connection is then made between the gene-

rator and receiver by an union pipe, as at figs. 255 and 256, and then the valves of both vessels being opened, the carbonic acid passes, by a process of rapid distillation, from the former into the latter. This transfer is accelerated in proportion as the temperature of the two vessels differs; hence warm water is employed in charging; an increase of heat also ensues by the acid mixing with the water; the receiver also should be put into cold or iced water.

The valves are now to be closed, the vessels separated, and the contents of the generator discharged, and the same process of charging is to be repeated many times.

Mr. Addams found that only about one-third of the carbonic acid of the generator passed into the receiver in the ordinary management of this process; he was, therefore, led to construct a pump to force water into the lower end of the generator, equipped with two valves, as figs. 261 and 262; and thus by filling the generator, the whole of the liquid carbonic acid is transferred into the receiver, and that too without the cooling of the receiver with ice; and by this plan an economy equal to two-thirds in material and time is effected. But in order to use

a pump to use a gauge to observe when the generator was filled and all the carbonic acid displaced. The gauge for this purpose is shown (inserted in the union-pipe) at G G', fig. 263. It consists, essentially, of a strong glass tube, secured within a metal cylinder formed by boring out the centre of the solid: this last has slits cut parallel to its length on opposite sides; then as the passage into the receiver is through this glass gauge, it is easy to observe the instant when the saline fluid of the generator rises into it, and then to stop the action of the pump; and, consequently, no liquid but the carbonic acid enters the receiver.

He has attached a gauge of similar construction to a double-valved receiver, and with it is enabled to see the carbonic acid at any time, to measure the quantity transferred from this vessel into others, and to obtain certain useful information respecting the quantity produced by different modes of management.

Within the receiver, when charged, there is liquid carbonic acid below, and highly condensed gas above it: upon opening the valve the expansion of the gas forces the liquid up the central tube *TT* (fig. 258), and then a part of it instantly passes into the state of gas at the orifice of the outlet *s* (fig. 257), and another portion is frozen into a white snow-like solid, affording a beautiful instance of the sudden transference of heat when a liquid expands into a gas. This white matter, or solid carbonic acid, is blown out in finely-divided particles, and to collect it, an ingeniously constructed recipient or *draw-out box* is used, being the contrivance of M. Thilorier. It consists of a brass cylindrical case (fig. 264), having tubular handles affixed to its ends. Plates of pierced brass are fixed before the outlet of each handle, as shown by *f'f* (fig. 265); these act as sieves to keep back the solid acid and allow the gas to pass out.

The box has a short tube joined to the side, as in section fig. 266, *M*, so as to form a tangent to the inner circle of the case. And opposite to this pipe is placed a bent plate of brass, *O* (fig. 266), in order to prevent the violence of the intruding gas from blowing the solid matter into such fine powder as would enable it to pass through the perforated discs. For the purpose of taking out the solid, the box is made separable by one end sliding a little within the other, and retainable together by two obliquely grooved holders placed on opposite sides of the joint. This draw-out box is united to the receiver by the union-piece (fig. 267), the nozzle *N*, having a small hole through it, and upon this the tangent-tube of the box fits.

From 2·75 lbs. of bicarbonate of soda of average quality, Mr. Addams obtains about 19000 cubic inches of carbonic acid of ordinary pressure and temperature: by the first method, without the pump, 13000 of these are left in the generator, and, of course, escape on opening, unless the receiver be kept colder and a longer time allowed for the transfer than is convenient in a general way of management. He finds that about 12·5 cubic inches of liquid carbonic acid are conveyed into the receiver from each charge of the generator, provided the temperature of the receiver be at 54°. But when the pump is employed the only loss of acid is that which is entangled with the sulphate of soda, and which generally measures 1100 cubic inches, under atmospheric pressure; and in this way about 37 cubic inches of liquid carbonic acid are sent into the receiver, at each charging, instead of 12·5.

The tension of carbonic acid gas as it exists above the liquid depends

upon the temperature, and Mr. Addams has given the pressures through a considerable range of the thermometer, namely, from zero to 150° , at intervals of each 5° . The following table includes the force for each successive 10th degree; by which it will be seen, that, similar to vapours of all kinds resting upon their respective liquids, the tension increases in a higher ratio than the temperatures. He employed a pressure gauge of 43 inches in length, in the experiments which afforded data for this table; and many of the results were confirmed by a kind of loaded safety valve*.

Temperature.	Pressure in lbs. per sq. inch.	Pressure in Atmospheres per sq. inch.	Temperature.	Pressure in lbs. per sq. inch.	Pressure in Atmospheres per sq. inch.
Zero	270.9	18.06	80°	741.3	49.42
10°	300.	20.	90	837.6	55.84
20	346.65	23.11	100	934.8	62.32
30	398.1	26.54	110	1040.25	69.35
40	457.35	30.49	120	1151.7	76.78
50	520.05	34.67	130	1264.65	84.31
60	586.35	39.09	140	1379.55	91.97
70	658.05	43.87	150	1495.65	99.71

Liquid Carbonic Acid is limpid, colourless, and extremely fluid. Its specific gravity at 32° is 0.83: it distils readily and rapidly at the difference of temperature between 32° and 0° . Its refractive power is much less than that of water. No diminution of temperature alters its appearance. In Mr. Faraday's endeavours to open the tubes at one end, they always burst into fragments with powerful explosion. Mr. Brunel endeavoured to apply this liquid as a mechanical agent for the production of motive power: of this attempt a short account will be found in the *Quarterly Journal* (Old Series, xxi. 131).

Liquified carbonic acid exhibits a remarkable property in respect to its expansibility by heat, in which it appears, from M. Thilorier's statement (*Ann. de Chim. et Phys.*, LX. 427), to exceed even that of the gaseous acid, or of air. Thus from (0° to $+30^{\circ}$ centigrade) 32° to 86° (Fahrenheit), its bulk increases from 20 to 29, which is 4 times greater than the dilatibility of air within the same range. From 0° to $+30^{\circ}$ (cent.) the pressure of the vapour furnished by the liquified gas, rises, according to Thilorier, from 36 to 73 atmospheres, which is one atmosphere of increase for each centigrade degree. Liquid carbonic acid is insoluble in water and in the fat oils, but it is soluble in all proportions in alcohol, ether, oil of turpentine, and carburet of sulphur.

A jet of liquid carbonic acid, emitted upon the bulb of a spirit thermometer, sinks it to -90° (cent.), but the general frigorific effects do not correspond with this depression of temperature, in consequence of the almost entire want of conducting power in the gas, and its little capacity for heat. But as the case is different with regard to *vapours*, Thilorier tried the effect of a jet of liquid carbonic acid mixed with ether, and in this way he succeeded in producing a *cold blow-pipe*, which froze 50 grammes of mercury in a small glass capsule in a few seconds. Mr.

* In this table the atmospheric pressure is assumed to be = 15 lbs.

Addams informs me that at common temperatures liquid carbonic acid acts with extreme slowness upon potassium and sodium, requiring a month to convert a piece of potassium, of the size of a pea, into carbonate of potassa: he observes that the potassium apparently derives its requisite equivalent of oxygen from the conversion of carbonic acid into carbonic oxide, inasmuch as no carbon is deposited when proper precautions have been taken to deprive the acid of water by fused chloride of calcium.

Solid Carbonic Acid.—Thilorier first showed that carbonic acid may be obtained in a *solid* form by suffering a jet of the liquid acid to issue into a small phial, which immediately was lined by a white flocculent powder, consisting of the carbonic acid solidified or frozen by the intense cold resulting from its own expansion. It is easily obtained in large quantity by the methods above described. In the solid state it moves about upon any polished surface, like a drop of water upon white-hot iron, and slowly disappears. Mr. Addams found the surfaces from which it had evaporated, in a negatively electrical state. When handled it feels like snow, and owing to its low conducting power it does not evaporate very rapidly nor feel extremely cold, though its actual temperature is probably as low as 148° below the 0° of Fahrenheit. When a little mercury is put into a saucer and covered by solid carbonic acid, the addition of a few drops of good ether forms a semifluid mass, by the contact of which the mercury is immediately frozen. In this way Mr. Addams succeeded in freezing ten pounds of mercury in less than eight minutes; and in further illustration of the extraordinary relations of this substance, he informs me that he has kept a large lump of the solid carbonic acid for a minute, in a red-hot crucible, and afterwards frozen a pound of mercury with it. When a piece of the solid acid is put into a gas bottle, it gradually becomes gas, which may be collected as usual over water; or its conversion into the gaseous state may be more strikingly observed by letting up a small piece of it into an inverted jar of water. The following modification of this experiment I first saw performed by Professor Graham. A tall stoppered air-jar is inverted in the pneumatic trough, and half filled with oxygen; a piece of solid carbonic acid is then let up into it, by which the lower half of the jar soon becomes filled with very cold carbonic acid gas; if the glowing wick of a taper, attached to a long wire, be then plunged through the upper opening of the jar into the oxygen, it is instantly kindled into flame, but extinguished by causing it to descend into the inferior atmosphere of carbonic acid; and by a little care the wick may be left glowing, and then lifted into the oxygen, when it again bursts into flame: this alternate extinction and reproduction of flame may in this way be many times repeated.

Properties of Carbonic Acid Gas.—This gas is perfectly unrespirable, for on attempting to breathe it in a pure state the epiglottis is spasmodically closed, and no air entering the lungs, suffocation is the direct consequence. When it is so far diluted with air as to admit of being received into the lungs, it then operates as a narcotic poison, producing drowsiness and insensibility, and this, even when a candle will burn in the mixture. (CHRISTISON.) Hence the danger of a confined room in which a pan of burning charcoal is placed. Butterflies, and other insects,

of which it is desired to preserve the colours unimpaired, may sometimes be conveniently suffocated by this gas. Carbonic acid immediately extinguishes the flame of a taper, and this even when considerably diluted with atmospheric air. In this way its weight may be conveniently shown by placing a lighted taper at the bottom of a tall glass jar, and then pouring the gas out of a bottle into it, in the manner of a liquid; it descends, and extinguishes the flame, and will remain for some time in the lower part of the vessel. Like other gases, however, notwithstanding its specific gravity, it soon blends with, and diffuses itself through, the mass of surrounding air. In wells, and in some caverns, carbonic acid frequently occupies the lower parts, while the upper parts are free from it. The miners call it *choak damp*. In these cases it issues from crevices in the earth, and is produced by unknown sources. In consequence also of its weight, it may be collected without the pneumatic apparatus, as it issues from a tube passed near the bottom of a dry bottle: it soon displaces the common air, and may be traced, flowing over the neck of the bottle, by holding a taper to it, which is then extinguished. (See this mode of collecting gas described at p. 366.)

When water is agitated in carbonic acid, it takes up its own volume of the gas at common temperature and pressure, and acquires a very slight increase of specific gravity. Under a pressure of two atmospheres it dissolves twice its volume, and so on. It thus becomes brisk and tart, and reddens delicate vegetable blues. If litmus paper, thus reddened, be exposed to the air, the blue colour returns as the acid evaporates; hence an easy distinction between the paper reddened by any of the more fixed acids in which the change of colour is permanent. In the same way, infusion of litmus thus reddened becomes blue when the carbonic acid is expelled by boiling. By freezing, boiling, or exposure to the vacuum of the air-pump, the gas is given off, and it gradually makes its escape when exposed to air, collecting in small bubbles upon the sides of the containing vessel, and passing off with especial rapidity when any foreign substances are thrown in, or when any substance is dissolved in the water; thus it is, that sugar added to soda-water, cyder, champagne, or other similar carbonated liquors, occasions in them an immediate and abundant effervescence.

Porter, ale, cyder, and many other beverages, derive their brisk-

ness from carbonic acid. The effervescent quality of many mineral waters is also referable to the presence of this gas, and they are often imitated by condensing carbonic acid into water, either by a condensing pump, of which a description is given by Mr. Pepys (*Quarterly Journal of Science and Arts*, iv. 305), or by a *Nooth's apparatus*, as represented in the preceding wood-cut (fig. 268). It consists of three vessels, the lowest, *a*, flat and broad, so as to form a steady support; it contains the materials for evolving the gas, such as pieces of marble and dilute hydrochloric acid, of which fresh supplies may occasionally be introduced through the stopped aperture. The gas passes through the tube *b*, in which is a glass valve opening upwards, into the vessel *c*, containing the water or solution intended to be saturated with the gas, and which may occasionally be drawn off by the glass stop-cock. Into this dips the tube of the uppermost vessel *d*, which occasions some pressure on the gas in *c*, and also produces a circulation and agitation of the water. At the top of *d* is a heavy conical stopper, which acts as an occasional valve, and keeps up a degree of pressure in the vessels.

The presence of carbonic acid is instantly detected by *lime water*, which it renders turbid, and causes a deposit of a white powder, which is *carbonate of lime*. The addition of water saturated with carbonic acid, to lime-water, also occasions a milkiness from the same cause. If excess, either of the gas or of its aqueous solution, be added to the lime-water, the precipitate is re-dissolved, carbonate of lime being soluble in carbonic acid. (See *Lime*.)

As all common combustibles, such as coal, wood, oil, wax, tallow, &c., contain carbon as one of their component parts, so the combustion of these bodies is always attended by the production of carbonic acid. It is also produced by the respiration of animals; hence it is detected, often in considerable proportion, in crowded and illuminated rooms, which are ill ventilated, and occasions difficulty of breathing, giddiness, and faintness. In the atmosphere it may also be detected, as has already been mentioned (page 448). Saussure found it in air from the summit of Mont Blanc; and Humboldt discovered it in air brought by Garnerin from a height of twenty thousand feet, to which he had ascended in a balloon. Its production in the lungs is easily shown, by blowing the expired air through lime-water by means of a small tube; it becomes milky, and soon deposits carbonate of lime. The quantity of carbonic acid ejected from the lungs at each ordinary expiration varies a little at different times of the day. (See *Respiration*.) According to Dr. Prout, it amounts on an average to 3.45 per cent. of the expired air, its limits being 3.3 and 4.1 per cent.

As carbonic acid is often retained in combination by feeble affinity, so it is evolved from some of the *carbonates* by the simple operation of heat. Thus chalk, when heated, gives out carbonic acid, and becomes *quicklime*, but in these cases its escape is generally facilitated by the copresence of air or aqueous vapour; in other cases the carbonates may be heated to redness without the slightest tendency to the evolution of carbonic acid, as is the case with the carbonates of potassa and soda. Carbonic acid is also displaced by most of the other acids; and if dilute nitric, hydrochloric, or sulphuric acid be poured upon the carbonates, the presence of carbonic acid is indicated by *effervescence*.

Carbonic acid retards the putrefaction of the greater number of animal substances: applied to the roots of vegetables in aqueous solution, it is generally propitious to their growth, as will be more fully shown in a future chapter. Most plants thrive in an atmosphere containing not more than a tenth or twelfth part of carbonic acid; and under certain circumstances, which will afterwards be explained, they decompose it, and evolve oxygen.

At high temperatures, carbonic acid is decomposed by several of the metals, and converted into carbonic oxide; and potassium and sodium, when sufficiently heated, burn in it, and are converted into potassa and soda, whilst the carbon or charcoal of the gas is thrown down in the solid form. There are some other substances which, at high temperatures, are capable of decomposing carbonic acid, and abstracting part of its oxygen; thus, if a mixture of two parts of hydrogen and one of carbonic acid, by volume, be passed through a red-hot tube in the apparatus represented at p. 431, water is formed, and carbonic oxide passes into the receiver *d*, mixed with the excess of hydrogen. Dr. Henry also found that by passing a succession of electric sparks through carbonic acid confined over mercury, a portion of it was resolved into carbonic oxide and oxygen. (*Phil. Trans.*, 1809, 448.) When the carbonic acid which escapes decomposition has been washed out by solution of potassa, an electric spark inflames the residuary mixture, the oxygen and carbonic oxide again uniting and reproducing carbonic acid.

Phosphorus, when heated in carbonic acid, does not decompose it; whence it might be inferred that carbon possessed a stronger affinity for oxygen than phosphorus; and such an inference is sanctioned by the decomposition of phosphoric acid, at high temperatures, by charcoal: but if complex attraction be brought into action, the case is altered, as was first shown by Tennant (*Phil. Trans.*, 1791, p. 182), and afterwards by Pearson (*Phil. Trans.*, 1792, p. 280). Thus it is, that certain carbonates are decomposed, at high temperatures, by phosphorus: if the vapour of phosphorus be passed over ignited carbonate of lime, or carbonate of soda, charcoal is deposited, and phosphate of lime or phosphate of soda produced.

If carbonic acid be passed over red-hot charcoal, it becomes converted into carbonic oxide, by taking up an additional proportion of base. The blue flame, often seen upon the surface of a charcoal fire, arises from the combustion of the carbonic oxide formed in this way; the air entering at bottom, forms carbonic acid, which, passing through the red-hot charcoal, becomes converted into carbonic oxide. At a bright red heat, iron and zinc decompose carbonic acid, by abstracting a portion of its oxygen, and forming oxide of iron or of zinc, and carbonic oxide.

It has been above stated, that when carbon is burned in oxygen gas, carbonic acid is formed equal in volume to that of the oxygen, so that the difference of specific gravity between oxygen and carbonic acid leads to the quantity of carbon which it contains, and the weight of pure carbon taken up by a given bulk of pure oxygen gas, may thus be directly determined by experiment. Assuming the specific gravity of carbon vapour to be 0.84, and that of oxygen gas 1.11, and that a volume of carbonic

acid consists of one volume of oxygen, and half a volume of carbon vapour, its specific gravity should be $(1.11 + .42) = 1.52$; or

		Grains.
50	cubic inches of carbon vapour, weighing	12.7
100	„ oxygen gas „	34.6
100	„ carbonic acid should weigh	47.3

Both these statements closely agree with the experimental result; carbonic acid, therefore, consists of

CARBONIC ACID AND AMMONIA. CARBONATE OF AMMONIA. ($A + car'$).
—When one volume of carbonic acid and two volumes of ammonia are mixed in a glass vessel over mercury, the gases are slowly condensed into a white crystallized solid, which lines the interior of the vessel, and which has been termed *carbonate of ammonia*. The product must at all events

* It has been customary to represent carbonic acid as a compound of *one* volume of the vapour of carbon and *one* volume of oxygen, the *two* volumes being condensed into *one* of carbonic acid, and, upon this principle the specific gravity of the vapour of carbon, in reference to the specific gravity of hydrogen, has been assumed as 6 to 1, or in reference to that of oxygen as 6 to 16. Upon this hypothesis, therefore, a volume of *carbonic oxide* would consist of one volume of the vapour of carbon and half a volume of oxygen, or

Carbon. 6	Oxygen 8	=	Carbonic Oxide.
			14

and a volume of *carbonic acid* would consist of one volume of carbon vapour and one volume of oxygen, or

Carbon. 6	Oxygen. 16	=	Carbonic Acid.
			22

But, as observed by Mitscherlich (*Lehrbuch der Chemie*, i. 84), this view of the specific gravity of carbon vapour is incon-

sistent with analogous gaseous combinations, and, as we cannot determine the point *experimentally* (as with sulphur and phosphorus), analogy is our only guide. And as we find, in all other cases, that when *one* volume of one gas combines with *one* volume of another, no condensation ensues (one volume of nitrogen and one of oxygen forming *two* of nitric oxide, and one volume of hydrogen and one of chlorine forming *two* volumes of hydrochloric acid, &c.) but that, on the other hand, condensation does ensue when one volume of one gas combines with *half* a volume of another (one volume of nitrogen and half a volume of oxygen forming *one* volume of nitrous oxide, and one volume of hydrogen and half a volume of oxygen forming one volume of steam), so it is probable that one volume of carbonic oxide is constituted of half a volume of carbon vapour and half a volume of oxygen; and that one volume of carbonic acid is constituted of half a volume of carbon vapour and one volume of oxygen. Upon this view of the subject, therefore, the specific gravity of carbon vapour would be 0.84 instead of 0.42; or, in reference to hydrogen, 12 instead of 6; and, as far as the theory of *volumes* is concerned, carbon would thus resemble oxygen.

contain the elements of ammonia and carbonic acid in the following proportions:—

Ammonia	. . . 1	. . . 17	. . . 43.5
Carbonic acid	. . . 1	. . . 22	. . . 56.5
	<hr/> 1	<hr/> 39	<hr/> 100.0

The above results, however, are only obtained when the gases are perfectly dry, for if any moisture be present more carbonic acid is taken up, and a sesqui or bicarbonate of ammonia result. This apparently anhydrous salt has not been accurately examined, but as there is no other instance of the direct union of ammonia with an anhydrous oxyacid, it has been suggested by Dumas that it may be an amide, or a compound of amidogen, carbonic oxide, and water: for it is obvious that the ultimate elements of the supposed neutral carbonate of ammonia (namely $n+3h+car+2o$) may be arranged as $(n+2h)+(car+o)+(h+o)$.

BICARBONATE OF AMMONIA. ($A+2car'$).—If water be present, ammonia and carbonic acid condense each other in equal volumes, and consequently a bicarbonate is the result; but it does not exist in an anhydrous state. It is also formed when the common carbonate is kept for some time exposed to air in imperfectly closed vessels, in which case it loses ammonia, and becomes nearly inodorous, and less soluble in cold water. When carbonic acid is passed through a saturated aqueous solution of the common carbonate, this salt is also produced, and may be brought to crystallize; it forms right rhombic prisms, soluble in about 8 parts of cold water; inodorous, and of little taste; containing, according to Berzelius, 22.7 per cent. of water. The salt consists, therefore, of

Ammonia 1	. . . 17	. . . 21.5	. . . R. Phillips.	21.16
Carbonic acid 2	. . . 44	. . . 55.7	. . .	55.50
Water 2	. . . 18	. . . 22.8	. . .	23.34
Bicarbonate of ammonia	1	<hr/> 79	<hr/> 100.0		<hr/> 100.00

In reference to the ammonium theory this salt has been termed a bicarbonate of oxide of ammonium, in which case the elements of one of the atoms of water must be supposed to have combined with those of the ammonia to form oxide of ammonium; and under this view the following would be the constitution of the salt $(n+4h+o)+2(car+2o)+(h+o)$. Graham calls it a carbonate of water and of oxide of ammonium, and represents it as follows. $(car+2o)+(h+o)+(n+4h+o)+(car+2o)$

SESQUICARBONATE OF AMMONIA. ($A+1\frac{1}{2}car'$).—The carbonate of ammonia of commerce is generally met with in cakes broken out of the subliming vessel, being obtained by sublimation from a mixture of sulphate or hydrochlorate of ammonia, and carbonate

of lime. When the hydrochlorate is used, the results of the decomposition are carbonate of ammonia, water, and chloride of calcium, the two former being in combination, so that a *hydrated carbonate of ammonia* is always obtained. Supposing the materials perfectly dry, the water is formed by the union of the hydrogen of the hydrochloric acid with the oxygen of the lime, as shown in the preceding diagram.

Phillips has shown (*Quarterly Journal*, vii. 294), that this carbonate of ammonia consists of

Ammonia	1	. . .	17	. . .	28.8
Carbonic acid . . .	1½	. . .	33	. . .	56.0
Water	1	. . .	9	. . .	15.2
<hr/>					
Sesquicarbonate of ammonia	1		59		100.0

As far, therefore, as relates to the proportion of the carbonic acid to the ammonia, this salt is intermediate between the carbonate and bicarbonate, or a *sesquicarbonate of ammonia*. Its odour is pungent; its taste hot and saline; it reddens turmeric, and has an alkaline reaction upon other vegetable colours. It is much used as a stimulant and antacid in medicine, and is commonly called *smelling salts*. A pint of water at 60° dissolves rather less than four ounces. This solution is directed in the *Pharmacopœia*, under the name of *Liquor Ammonia Sesquicarbonatis*. If a hot saturated solution of this salt be made in a close vessel, and suffered to cool, it deposits octoëdral crystals. Exposed to air, it loses ammonia, and becomes the hydrated bicarbonate above described.

CARBON AND CHLORINE. CHLORIDES OF CARBON.—For our knowledge of the compounds of carbon with chlorine we are indebted to Mr. Faraday (*Phil. Trans.*, 1821, p. 47). The circumstances under which they combine have been more recently investigated by Regnault (*Ann. de Ch. et Ph.*, LIX. 151, and LXX. 104). By exposing carburetted hydrogen, mixed with great excess of chlorine, to the action of light, a white crystalline substance is formed, which, when purified by washing with water, is a *perchloride of carbon*. It is formed as follows:—A glass vessel, capable of holding about 200 cubic inches, is properly mounted, with a stop-cock, and exhausted upon the air-pump: it is then nearly filled with chlorine, and afterwards placed in connexion with a jar of olefiant gas standing over water, and, as much as can enter having passed in, the cocks are shut, and the whole left for a short time: when the fluid compound of chlorine and carburetted hydrogen (described further on) has formed, the cocks are reopened, and a fresh portion of carburetted hydrogen rushes in, in consequence of the condensation which has taken place; this is left, as before, to combine with the remaining chlorine, and the process continued, until no further action ensues, and the vessel is, in fact, full of carburetted hydrogen: chlorine is then similarly admitted, in repeated portions, and, ultimately, a quantity of the liquid hydrochloride of carbon is obtained, with an atmosphere of chlorine above it: in this state it is exposed to the direct rays of the sun. The chlorine speedily disappears, and hydrochloric acid is formed: this is absorbed by the admission of a little water; another atmosphere of chlorine is then admitted, and exposure to the sun repeated; by continuing these opera-

tions, the whole of the hydrogen is at length abstracted in the form of hydrochloric acid, and crystals are formed in the liquid; these are to be collected, washed, and pressed between bibulous papers, then introduced into a glass tube, and sublimed by a spirit-lamp; the pure substance, with water, will rise at first, but the last portions will be partially decomposed, hydrochloric acid will be liberated, and charcoal left. The sublimed portion is then to be dissolved in alcohol, and poured into a weak solution of potassa, by which the substance is thrown down, and the hydrochloric acid neutralized and separated; then wash the substance with repeated affusions of water, collect and dry it, first between folds of paper, and then in the exhausted receiver of the air-pump. If quite pure, it sublimes without any change, and a small portion dissolved in ether gives no precipitate with nitrate of silver.

SESQUICHLORIDE OF CARBON ($car + 1\frac{1}{2}c$) thus purified is nearly tasteless; its odour resembles camphor; its specific gravity is about 2; it is a non-conductor of electricity, and powerfully refracts light. It is volatile, and in close vessels fuses at 320° ; it boils at 360° , and may be distilled without decomposition: its vapour again condenses in crystals as it cools. It is not very combustible, but burns when held in the flame of a spirit-lamp, with the emission of much smoke and acid fumes. It burns vividly in oxygen gas. It is insoluble in water, but readily soluble in alcohol and ether; these solutions deposit arborescent and quadrangular crystals. It also dissolves in volatile and fixed oils. It is scarcely acted upon by alkaline and acid solutions, but most of the metals decompose this substance at a red heat. Potassium burns brilliantly in its vapour, causing the deposition of carbon, and the production of chloride of potassium. The metallic oxides also decompose it at high temperatures, producing metallic chlorides, and carbonic acid or oxide, according to the proportion of oxygen present; no water is produced, showing the absence of hydrogen in the compound. It appears, from various analytical experiments upon this compound, among which may be mentioned its decomposition by passing it through red-hot peroxide of copper, that it is a *sesquichloride of carbon*, consisting, therefore, of

Carbon	1	. .	6	. .	10
Chlorine	$1\frac{1}{2}$. .	54	. .	90
Sesquichloride of carbon	1		60		100

This compound is represented by Regnault by the formula ($2\ car + 3\ c$), the density of its vapour as determined by experiment being 8.157, or 120 in reference to hydrogen as=1, and as

		Sp. Gr.
1 volume carbon	} = 2 atoms	0.84

PROTOCHLORIDE OF CARBON. (*car* + *c*).—When the above sesquichloride or perchloride of carbon is passed through a red-hot tube containing fragments of rock-crystal to increase the heated surface, it gives off a portion of chlorine, and is converted into a liquid *protochloride of carbon*. It is a limpid colourless fluid, specific gravity 1·55, and not combustible, except retained in the flame of the spirit-lamp, when it burns with a yellow flame, much smoke, and fumes of hydrochloric acid. It does not congeal at 0°; it rises in vapour at about 165°. It is insoluble in water, but soluble in alcohol, ether, and the oils. It is not affected by the acids or alkalis, nor, at common temperatures, by solutions of silver. It dissolves chlorine, iodine, sulphur, and phosphorus. It affords, when decomposed, 17 carbon + 83 chlorine; whence it may be inferred to consist of

Carbon	1	6	14·3
Chlorine	1	36	85·7
<hr/>			
Protochloride of carbon	1	42	100·0

According to Regnault the density of the vapour of this protochloride of carbon, as determined by experiment, is 5·820 (or 84 in reference to hydrogen as = 1), its formula, therefore, is probably (*2car* + *2c*), inasmuch as

DICHLORIDE OF CARBON. SUBCHLORIDE OF CARBON. (*2 car* + *c*).—This compound was accidentally obtained in Sweden, whence it was brought by Julin, and submitted to analysis by Phillips and Faraday. (*Ann. of Phil.*, N. S., i. 216, and ii. 150.) It is a solid crystalline body, volatile by heat, without decomposition, and condensing into crystals. It is insoluble in water, but soluble in alcohol, ether, and essential oils. It sinks in water. It burns with a red flame, giving off much smoke, and fumes of hydrochloric acid. Acids do not act on it. When its vapour is highly heated in a tube, chlorine is given off, and charcoal deposited. Potassium burnt with it forms chloride of potassium and liberates charcoal. Its vapour, detonated over mercury, with oxygen, formed carbonic acid and chloride of mercury: passed over hot oxide of copper, it formed a chloride of copper and carbonic acid; and over hot lime, it occasioned ignition, and produced chloride of calcium and carbonic acid. The results of its analysis by oxide of copper, show that it consists of

Carbon	2	12	25
Chlorine	1	36	75
<hr/>			
Dichloride of carbon	1	48	100

This compound was said to have been formed during the distillation of protosulphate of iron and nitre (both salts no doubt impure). All attempts at producing it by other means have failed, nor has it

been converted into either of the other chlorides. (*Phil. Trans.*, 1821, p. 392.)

CARBON AND IODINE. SESQUIODIDE OF CARBON.—This compound of carbon and iodine was first obtained by Serullas, and considered as a hydriodide of carbon. (*Ann. de Chim. et Phys.*, xx. 163, and xxii. 172.) It was subsequently examined by Mitscherlich. (*Ann. de Chim. et Phys.*, xxvii. 85.) It is produced in the form of a yellow precipitate, when a saturated solution of iodine in alcohol is mixed with a strong alcoholic solution of potassa or soda: part of the iodine combines with the potassium or sodium, and the liberated oxygen unites to the hydrogen of the alcohol to form water, whilst another part of the iodine combines with the carbon of the alcohol. Iodide of carbon is of a lemon-yellow colour, and a sweetish taste. It crystallizes in brilliant spangles; its smell somewhat resembles that of saffron: its specific gravity is nearly 2. It is not sensibly soluble in water, but dissolves in 80 times its weight of alcohol of 0·825 specific gravity at 60°, and in 25 times at 95°. One part dissolves in 7 of ether. It also dissolves in fat and volatile oils; and when its solution in oil of lemon-peel is exposed to light, it is decomposed, and charcoal and iodine are deposited. Sulphuric, sulphurous, nitric, and hydrochloric acids have no action upon it, nor has aqueous solution of chlorine; but gaseous chlorine decomposes it, and forms chloride of iodine, and a white substance, which is probably a chloride of carbon. At common temperatures it gradually evaporates when exposed to air, and at 212° volatilizes without decomposition; between 240° and 248° it enters into fusion, and is soon decomposed, giving rise to vapours of iodine and a brilliant charcoal. If moisture be present, carbonic and hydriodic acids may be formed. (*Ann. de Chim. et Phys.*, xxxvii. 85.) Serullas analyzed this compound by passing it over ignited peroxide of copper. (*Ann. de Chim. et Phys.*, xxxix. 230.) It appears to be a *sesquiodide* ($car + 1\frac{1}{2}i$), and to consist of

Carbon	1	6	3·1
Iodine	$1\frac{1}{2}$	189	96·9
Sesquiodide of carbon	1	195	100·0

PROTIODIDE OF CARBON. ($car + i$).—This compound, also mistaken by Serullas for a hydriodide (*Ann. de Chim. et Phys.*, xxv. 314), is prepared by triturating together equal parts of dry sesquiodide of carbon, and perchloride of phosphorus, and gently heating the mixture in a tubulated retort, the beak of which dips into water; a liquid passes over, which falls to the bottom of the water, and which, when carefully separated and mixed with four or five parts of sulphuric acid, is thus freed from hydrochloride of carbon, and remains at the bottom of the acid; it is ultimately separated, and having been washed with a solution of potassa, and lastly with water, is the pure *iodide of carbon*. It is a heavy, yellow liquid, of a peculiar ethereal odour and sweet taste; very little soluble in water, and not congealed at 32°. Exposed to air it gradually reddens. It does not act upon potassium; in the flame of a candle it gives out iodine. It is decomposed at a red heat when passed over peroxide of copper, and

from the produced carbonic acid, Serullas inferred (*Ann. de Chim. et Phys.*, xxxix. 231) that it consists of

Carbon	1	6	4.58
Iodine	1	126	95.42
<hr/>			
Protiodide of carbon	1	132	100.00

Recent experiments have thrown some doubt as to whether the above compounds are or are not free from hydrogen.

CARBON AND BROMINE. BROMIDE OF CARBON.—This compound was also discovered by Serullas (*Ann. de Chim. et Phys.*, xxxiv. and xxxix.), and is formed by adding two parts of bromine to one of the solid iodide of carbon, and just enough solution of potassa to occasion the disappearance of the free iodine. A liquid bromide of carbon will appear at the bottom of the solution, which is to be separated by a funnel or otherwise, but without washing with water, and allowed to stand till it has become quite clear; during this time, crystals of iodate of potassa form upon the surface; the clear fluid beneath is to be withdrawn, and put into a weak solution of potassa, for the purpose of decomposing a little protiodide of carbon formed at the same time: a little bromide is also decomposed, but that which remains is soon left in a pure state. The principal properties of this, (which is probably a *protobromide of carbon*,) and the differences between it and the liquid protiodide, are as follows: the bromide becomes solid, hard, and crystalline, at 32° , and remains solid up to 43° ; the iodide remains fluid in the lowest temperatures. The bromide gives red vapour; the iodide violet vapour, when heated in the flame of a spirit-lamp. Neither of them act upon water, but are slowly decomposed in weak alkaline solutions. (*Ann. de Chim. et Phys.*, xxxix. 225.) This compound, like the iodide, is by some suspected to contain hydrogen.

FLUORIDE OF CARBON is unknown.

CARBON AND HYDROGEN.—These elements unite in several proportions, and form many curious and important compounds, among which it is sometimes difficult to distinguish those which ought to be considered as distinct and definite combinations, from others which are probably indefinite mixtures of the former. These compounds are generally termed *hydrocarbons*, or *hydrocarburets*, and amongst them are some striking illustrations of one species of *isomerism* (from *ισος*, *equal*, and *μερος*, *part*), that is, of compounds differing, often essentially, in their physical or chemical properties, or both, and yet apparently produced by the union of the same elements bearing the same ratio to each other. Bihydrocarbon, or olefiant gas, and quadrihydrocarbon, or etherine, for instance, are in this predicament; when analyzed they are each found to consist of carbon, and hydrogen, in the same relative proportions, namely, 1 atom of carbon united to 1 atom of hydrogen; but the density of a volume of the former is to that of the latter, as 1 to 2; hence there are twice the number of simple atoms in an equivalent of etherine, that exist in an equivalent of olefiant gas; and assuming the density of hydrogen as = 1, that of olefiant gas is 14, and of etherine 28; hence we consider an atom of olefiant gas as constituted of 2 atoms of carbon, and 2 atoms of

hydrogen ($2\text{car} + 2\text{h}$), and an atom of etherine as constituted of 4 atoms of carbon, and 4 atoms of hydrogen ($4\text{car} + 4\text{h}$). Their respective volumes, equivalents, and densities, may, therefore, be represented thus; as will be obvious by referring to the following more detailed statement of their composition. Here, therefore, although the compounds are isomeric, they are represented by different equivalent numbers; but there are cases of *isomerism* in which the same elements are united in the same ratio, so as to produce compounds represented by the same equivalent number, yet essentially distinct in their chemical characters. It has been observed by Dr. Turner, that our notions of isomerism are quite consistent with our theories of chemical union, inasmuch as the same elements may be grouped, or combined in various ways, so as to give rise to compounds essentially distinct. Thus, the elements which in one form of arrangement constitute *nitrate of ammonia* ($2\text{n} + 5\text{o} + 3\text{h}$), in another constitute *nitrous oxide and water* $2(\text{n} + \text{o}) + 3(\text{h} + \text{o})$. Thus also the elements of sulphate of potassa ($\text{po} + \text{o} + (\text{s} + 3\text{o})$), may be united as expressed by the preceding formula, or as in the following ($\text{po} + \text{s} + 4\text{o}$), or they may be arranged into other aggregates.

Hydrogen.	Olefiant.	Etherine.
1	14	28

Of the compounds of CARBON and HYDROGEN, we shall here describe some of the most important of those which have the characters of distinct and definite combinations; reserving others to be noticed amongst *organic products*.

BIHYDROURET OF CARBON. DICARBURET OF HYDROGEN. LIGHT CARBURETTED HYDROGEN. FIRE-DAMP OF COAL-MINES. INFLAMMABLE AIR OF MARSHES. HEAVY INFLAMMABLE AIR. ($\text{car} + 2\text{h}$), or CH_2 .—Under these names an important variety of hydrocarbon is designated, which occasionally occurs pent up in cavities in coal-mines, (DAVY, *Phil. Trans.*, 1815,) and which is also said to be abundantly formed in stagnant pools during the spontaneous decomposition of vegetable matter, and to be procured by stirring up the fetid mud, and collecting the gas that rises in an inverted glass jar; in this state it is mixed with a little nitrogen and with carbonic acid; the latter may be separated by washing the gas in lime-water or a solution of caustic potassa. The gas procured from a *blower* in a coal-mine, after having been washed with lime-water, probably furnishes this compound in its purest state; but it does not appear that it can be produced artificially, unless it be admitted that a portion of the inflammable gas generated by the distillation of moist charcoal at a red heat, or by that of pit-coal, be similarly constituted.

Sir H. Davy found the specific gravity of this purified gas from a coal-mine to be 0.559, and compared with hydrogen as 8 to 1. 100 cubical inches weighed between 16 and 17 grains (or, according to Thomson, 18.2148 grains at the temperature of 32°), and nearly the same specific gravity is assigned to this gas (0.559) by Henry and Dalton. It is highly inflammable, burning with a yellow flame, and producing carbonic acid and water; it has a slightly disagreeable odour. It is not decomposed by electricity, but when passed through a white-hot

tube, deposits a portion of its carbon. Dry chlorine, even when aided by light, does not act upon it at common temperatures; but when the gases are moist and exposed to sunshine, a mutual action ensues; if there be excess of chlorine, carbonic and hydrochloric acid gases are produced. Passed with chlorine through a red-hot tube, or subjected to the electric spark, carbon is thrown down, and hydrochloric acid formed.

100 volumes of this gas require 200 of oxygen for perfect combustion, and the result is *water*, and 100 volumes of *carbonic acid*. 100 of carbonic acid contain 100 of oxygen, or half the quantity consumed; the remaining hundred volumes, therefore, must have combined with 200 of hydrogen to form water; hence, as

50	cubic inches of carbon vapour weigh	12.70
200	hydrogen gas	4.23
100	light carburetted hydrogen should weigh	16.93

which closely agrees with Davy's experimental result, and shows that this gas is constituted of

				Vols.	Sp. Gr.

Or,

$$\begin{array}{|c|c|} \hline \text{car} & h \\ \hline 6 & 1 \\ \hline & h \\ \hline & 1 \\ \hline \end{array} = \frac{\text{car} + 2h}{8}$$

Sir H. Davy made several experiments on the combustibility and explosive nature of this gas. He found that when 1 volume of the fire-damp was mixed with 1 of air, they burnt by the approach of a lighted taper, but did not explode; 2 of air and 3 of air to 1 of gas produced

similar results. When 4 of air and 1 of gas were exposed to a lighted candle, the mixture being in the quantity of 6 or 7 cubical inches in a narrow-necked bottle, a flame descended through the mixture, but there was no noise: 1 volume of gas inflamed with 6 of air in a similar bottle, produced a slight whistling sound: 1 of gas with 8 of air rather a louder sound: 1 with 10, 11, 12, 13, and 14, still inflamed, but the violence of combustion diminished. In 1 of gas and 15 of air, the candle burnt, without explosion, with a greatly enlarged flame; and the effect of enlarging the flame, but in a gradually diminishing ratio, was produced as far as 30 parts of air to 1 of gas. The mixture which seemed to possess the greatest explosive power was that of 7 or 8 volumes of air to 1 of gas; but the report produced by 50 cubical inches of this mixture was less than that produced by one-tenth of the quantity of a mixture of 2 parts of atmospherical air and 1 of hydrogen.

In reference to the *degree of heat* required to explode this gas mixed with its proper proportion of air, it was found that a common electrical spark would not explode 5 parts of air and 1 of the hydrocarburet, though it exploded 6 parts of air and 1 of the gas: but very strong sparks

from the discharge of a Leyden jar seemed to have the same power of exploding different mixtures of the gas as the flame of the taper. Well-burned charcoal, ignited to the strongest red-heat, did not explode any mixture of air and of the fire-damp; and a fire made of well-burned charcoal, *i. e.* charcoal that burned without flame, was blown up to whiteness by an explosive mixture containing the fire-damp, without producing its inflammation. An iron rod at the highest degree of red-heat, and at the common degree of white-heat, did not inflame explosive mixtures of the fire-damp; but, when in brilliant combustion, it produced the effect. The flame of gaseous oxide of carbon, as well as that of olefiant gas, exploded the mixtures of the fire-damp.

In respect of combustibility, then, this hydrocarburet differs most materially from the other common inflammable gases. Sir Humphry found that olefiant gas, which explodes mixed in the same proportion with air, is fired by both charcoal and iron heated to redness. Carbonic oxide, which explodes when mixed with 2 parts of air, is likewise inflammable by red-hot iron and charcoal; and hydrogen, which explodes when mixed with three-sevenths of its volume of air, takes fire at the lowest visible heat of iron and charcoal; and the case is the same with sulphuretted hydrogen. When 6 of air and 1 of the hydrocarburet were exploded over water by a strong electrical spark, the explosion was not very strong, and, at the moment of the greatest expansion, the volume of the gas did not appear to be increased more than one-half*. Nitrogen and carbonic acid mixed in different quantities with explosive mixtures of fire-damp, diminished the velocity of the inflammation. Nitrogen, when mixed in the proportion of 1 to 6 of an explosive mixture, containing 12 of air and 1 of fire-damp, deprived it of its power of explosion; when 1 part of nitrogen was mixed with 7 of an explosive mixture, only a feeble blue flame slowly passed through the mixture. One part of carbonic acid to 7 of an explosive mixture, deprived it of the power of exploding; so that its effects are more remarkable than those of nitrogen, probably, in consequence of its greater capacity for heat, and probably, likewise, of a higher conducting power connected with its greater density. These inquiries are very important, in reference to the existence of this variety of hydrocarburet, under the name of *fire-damp*, in coal-mines.

OLEFIANT GAS. HYDROGURET OF CARBON. BIHYDROCARBON. ($2CAR + 2h$.)—This gas was discovered in 1796, by the associated Dutch chemists, Bondt, Dieman, Van Troostwick, and Lawerenburg. (*Journ. de Phys.*, xiv. 178; *Ann. de Chim.*, xxi. 48.)

It is usually obtained by the decomposition of alcohol by sulphuric acid. For this purpose about two parts of the acid and 1 of alcohol (by measure) are put into a retort, and heated by a lamp; complicated changes ensue, which will be more fully explained under the article *Alcohol*; and soon after the mixture boils, the gas is evolved. It may

* This appears the expansion when the tube is very small; in larger tubes it is considerably more. The volume of the gas appears at least tripled during the explosion.

be collected over water, and should be well washed with lime-water, or solution of potassa, to abstract sulphurous and carbonic acids; it also retains a little ethereal vapour, which may be removed by agitating it with weak alcohol and afterwards with water. When thus purified its specific gravity is about '980, or compared with hydrogen as 14 to 1, and 100 cubical inches weigh about 30 grains. According to Thomson, its specific gravity is 0.9722 (the same as that of nitrogen and of carbonic oxide), and 100 cubic inches at the temperature of 32° weigh 31.8790 grains.

This gas has little odour when quite pure; it is inflammable, burning with a bright yellowish-white flame. Water absorbs about one-eighth of its volume. It is absorbed by sulphuric acid, no carbon being separated, nor sulphurous nor carbonic acid formed. In the course of several days, 1 volume of sulphuric acid absorbs between 80 and 90 of olefiant gas, and a peculiar compound results, capable of forming distinct salts. (Such compounds will be more particularly noticed under the articles *Naphthaline*, *Oil of Wine*, and *Sulphovinic Acid*.) It is unrespirable, and extinguishes flame. One part by volume requires, for perfect combustion, three of oxygen. When sulphur is heated in one volume of this gas, charcoal separates, and two volumes of sulphuretted hydrogen result. As hydrogen suffers no change of volume by combining with sulphur, it follows that olefiant gas contains two volumes of hydrogen condensed into one; hence the quantity of oxygen required for its combustion. This gas is also decomposed by heat alone, as by passing and repassing it through a red-hot tube of earthenware or metal; it then deposits its carbon, and is expanded into twice its original volume of pure hydrogen*.

When *one* volume of olefiant gas is detonated by the electric spark in a proper tube (which, on account of the violence of the explosion, should be very strong), with three volumes of oxygen, *two* volumes of carbonic acid are formed, and water is deposited: now two volumes of carbonic acid contain one volume of the vapour of carbon, and two volumes of oxygen, so that the other volume of oxygen must have condensed two volumes of hydrogen to form the water. Hence, *one* volume of olefiant gas must contain *one* volume of the vapour of carbon, and *two* volumes hydrogen: or, as

		Grains.
100	cubic inches of carbon vapour weigh	25.4
200	" hydrogen gas weigh	4.2
100	" olefiant gas should weigh	29.6

The following diagrams further illustrate the results of the combustion of one volume, or proportional, of olefiant gas with three volumes (or six proportionals) of oxygen.

* When *oil-gas*, compressed into vessels by a power equal to that of 30 atmospheres, is suddenly allowed to escape through a small aperture into the air, the *expansion* which it suffers appears to occasion in it a degree of chemical decomposition; for it deposits a black carbonaceous matter upon paper held in the current. (*Quarterly Journal*, N.S., i. 204.)

Before detonation.		After detonation.		
Olefiant Gas.	Oxygen.	Carbonic Acid.	Water.	
	Oxygen.			
	Oxygen.	$car + 2o$	Hydrogen.	Oxygen.
	Oxygen.	$car + 2o$	Hydrogen.	Oxygen.
	Oxygen.			
	Oxygen.			

Now as *one volume* of carbon vapour represents *two* equivalents, or proportionals, it is obvious, from the above statement, that olefiant gas must be composed of

	Saussure. Volumes.				Sp. Gr.	
Carbon . . . 2 . . . 12 . . . 85.7 . . . 85 . . . 1 . . .	2	12	85.7	85	1	0.843

Olefiant gas . . . 1 . . . 14 . . . 100.0 . . . 100 . . . 1 . . .	1	14	100.0	100	1	.980

Or, it may be thus represented:—

Carbon. 6		=	Olefiant Gas. 14
Carbon. 6			
Hydrogen. 1	Hydrogen. 1		

No compound has yet been identified (unless methylene be regarded as such) in which one atom of carbon is combined with one of hydrogen, and which would be represented by $(car + h)$, or by 0.5 volume of carbon vapour and 1 volume of hydrogen condensed into 1 volume: such a compound would have the equivalent number = 7, which would also be its specific gravity to hydrogen.

OLEFIANT GAS AND CHLORINE.—When olefiant gas is mixed with chlorine in the proportion of 1 to 2 by volume, the mixture, on inflammation, produces hydrochloric acid, and charcoal is abundantly deposited. If the gases be well mixed, and then inflamed in a tall and narrow glass jar (about 2 feet high and 4 inches in diameter), placed with its mouth upwards, the experiment is very striking; a deep-red flame gradually descends through the mixture, and a dense black cloud of carbon rises into the atmosphere; fumes of hydrochloric acid are at the same time formed, and a peculiar aromatic odour is evolved.

CHLORIDE OF HYDROCARBON. HYDROCHLORIDE OF CARBON. ($2car + 2h + c.$)—If instead of inflaming the mixture of one volume of olefiant gas and two volumes of chlorine, the gases be merely mixed, in equal volumes, over water, or in a clean and dry glass globe exhausted of air,

they act slowly upon each other, and a peculiar fluid is formed, which appears like a heavy oil: hence the term *olefiant gas*, applied to this hydrocarbon by the Dutch chemists. *Chloric ether* is the name applied to this fluid by Dr. Thomson, who, in 1810, ascertained that its component parts were chlorine and carburetted hydrogen. It was afterwards examined by MM. Robiquet and Colin (*Ann. de Chim. et Phys.*, i. and ii.), and more lately by Regnault (*Ann. de Chim. et Phys.*, lxxix. and lxxx.) The term *Hydrochloride of Carbon*, or *Hydrocarburet of Chlorine*, may properly be applied to it. It also may be formed by allowing a current of each gas to meet in a proper receiver; but there should be excess of olefiant gas, for if the chlorine be in excess, the liquid absorbs it. To purify it it should be washed in water, and then carefully distilled from fused chloride of calcium. It is transparent and colourless; its taste sweet, and somewhat acrid; its specific gravity = 1.2. It boils at 152°. According to Gay Lussac the specific gravity of its vapour is 3.44. It burns with a green flame, evolving hydrochloric acid, and largely depositing charcoal. It is decomposed when passed through a red-hot tube. As it is produced by equal volumes of chlorine and olefiant gas, it must be a compound of

					Volumes.	Sp. Gr.
Carbon	2	12	24	} Olefiant gas	1	0.98
Hydrogen	2	2	4			
Chlorine	1	36	72		1	2.47
Chloride of hydrocarbon	1	50	100		1	3.45

From Mr. Faraday's experiments, it appears that, by exposing this hydrochloride of carbon to the action of excess of chlorine, hydrochloric acid and chloride of carbon are the results. (See CHLORIDE OF CARBON.) And Mitscherlich states, that when it is exposed in the contact of water to the direct solar rays, it is converted into acetic ether and hydrochloric acid (*Lehrbuch*, 141).

Another view of the atomic constitution of this hydrochloride of carbon has been adopted by Regnault, which regards it as a combination of hydrochloric acid with the chloride of *acetyl*; the term *acetyl* being applied to a hypothetical hydrocarbon composed of $4\text{car} + 3\text{h}$, which is considered as the base of acetic acid, to which, therefore, I must here refer: but in reference to the present question it will be obvious that 2 atoms of hydrochloride of carbon contain the elements of chloride of acetyl and hydrochloric acid, for $2(2\text{car} + 2\text{h} + \text{c}) = (4\text{car} + 3\text{h}) + \text{c} + (\text{h} + \text{c})$. The origin and further application of these views will be apparent by reference to the theory of etherification, which is treated of under organic products: but they seem to me to involve discrepancies in respect to the densities of olefiant gas and of the vapour of the hydrochloride, and to confound olefiant gas with etherine or quadrihydrocarbon.

OLEFIANT GAS AND IODINE. IODIDE OF HYDROCARBON. HYDRIDIODE OF CARBON. HYDROCARBURET OF IODINE. ($2\text{car} + 2\text{h} + \text{i}$).—When iodine and olefiant gas are exposed to the action of light, they form a compound, first obtained by Faraday (*Phil. Trans.*, 1821, p. 72). Iodine and olefiant gas were put in various proportions, into retorts, and exposed to the sun's rays: after a while colourless crystals were formed, and a

partial vacuum was produced: the gas in the vessels was found to contain no hydriodic acid. The compound was purified by introducing a solution of potassa into the retort, which dissolved the free iodine; the substance was then collected, washed, and dried.

The hydriodide of carbon is a white crystalline solid, volatile without decomposition, and in some respects analogous to the hydrochloride of carbon; its taste is sweet, and its odour aromatic. It sinks in sulphuric acid of the specific gravity 1·85. It is a non-conductor of electricity. When highly heated it evolves iodine: it is not readily combustible, but when held in the flame of a spirit-lamp, burns, diminishing the flame, giving off abundance of iodine, and some fumes of hydriodic acid. It is insoluble in water, and in acid and alkaline solutions. It is soluble in alcohol and ether, and may be obtained in crystals from these solutions. The alcoholic solution is of a very sweet taste, but leaves a sharp sensation upon the tongue. Sulphuric acid does not dissolve it, but, when heated in the acid to between 300° and 400°, it is decomposed, apparently by the heat alone, and iodine and a gas (probably olefiant) are liberated. Boiling solution of potassa acts on it very slowly, but does gradually decompose it.

It was analyzed as follows, (*Quarterly Journal*, xiii.) Four grains were passed in vapour over heated copper in a green-glass tube; iodide of copper was formed, and pure olefiant gas evolved, amounting to 1·37 cubic inches, or 0·413 grains. Now 4 grains, *minus* 0·413 grains, leaves 3·587 of iodine, and 3·587 : 0·413 :: 126 : 14·3 nearly; the constitution of this compound, therefore, is analogous to that of the hydrochloride of carbon; it may be regarded as composed of

Carbon	2	12	8·63	} Olefiant gas	14
Hydrogen	2	2	1·44		
Iodine	1	126	89·93		
Iodide of hydrocarbon	1	140	100·00	1	140

OLEFIANT GAS AND BROMINE. HYDROBROMIDE OF CARBON. HYDROCARBURET OF BROMINE. ($2\text{car} + 2\text{h} + \text{b}$.)—When hydriodide of carbon is added to bromine, a hissing noise is produced, with much heat, and a bromide of iodine and fluid hydrobromide of carbon are formed. The bromide of iodine may be removed by water, and the hydrocarburet, with a slight excess of bromine, remains. It may be rendered colourless by a little alkali. If the hydriodide of carbon is in excess, but little of the hydrobromide is formed, but a subbromide of iodine.

The pure hydrobromide of carbon is colourless, heavier than water, of a penetrating ethereal odour, a very sweet taste, and very volatile. It does not change colour by exposure to air. At 22° it becomes solid, and breaks like camphor. It was formed, by Balard, by letting a few drops of bromine fall into a flask of olefiant gas. (*Ann. de Chim. et Phys.*, xxxiv.) It consists of

Carbon	2	12	13·04	} Olefiant gas	14
Hydrogen	2	2	2·18		
Bromine	1	78	84·78		
Bromide of hydrocarbon	1	92	100·00	1	92

BICARBURET OF HYDROGEN. ($6\text{ car} + 3\text{ h.}$).—For our knowledge of this combination we are indebted to Mr. Faraday. (*Phil. Trans.*, 1825, p. 440.) When certain oils are passed through red-hot tubes, as in the process for making gas for the purpose of illumination, there is at the same time a vapour produced, which, by considerable pressure, and by cold, may be reduced to a liquid state. Large quantities of this liquid were obtained at the Portable Gas-works, by subjecting the gas produced by the decomposition of whale oil, to a pressure of 30 atmospheres; this occasioned the deposition of the fluid, which was drawn off by a valve: it effervesced as it issued forth, and by the difference of refractive power, a dense transparent vapour was seen at the same time descending through the air. This effervescence immediately ceased, and the liquid was readily retained in ordinary stoppered bottles. 1000 cubical feet of good gas yielded nearly one gallon of it. It appeared as a thin light fluid, sometimes transparent and colourless, at others opalescent, being brown by transmitted, and green by reflected light; it had the odour of oil gas. Its specific gravity was 0.821: it did not congeal when cooled down to 0° ; was insoluble in water, readily soluble in alcohol, ether, and oils; slowly decomposed by nitric acid; and formed peculiar combinations with sulphuric acid, afterwards to be noticed. This fluid Mr. Faraday found to be a mixture of various bodies, differing in their degrees of volatility: to separate them, he carefully distilled successive portions of it into receivers, cooled to 0° , the receiver being changed with each rise of 10° in the retort, and the liquid retained in a state of incipient ebullition: it was thus found that the boiling-point was most constant between 176° and 190° , at which temperature considerable quantities passed over without any change in the degree. Of this rectified fluid a portion was exposed to a temperature of 0° , when part of it solidified, and being collected and dried by pressure, did not liquify till raised to 28° .

This portion constitutes the compound which we have above termed *Bicarburet of Hydrogen*. It appears as a colourless transparent liquid, having a peculiar odour like oil-gas mixed with that of bitter almonds. Its specific gravity is 0.85 at 60° . When cooled to a little below 32° , it solidifies, and contracts considerably on congealing. It does not conduct electricity; evaporates when exposed to air; boils at 186° . The specific gravity of its vapour is 2.77, or compared with hydrogen as 39 to 1. 100 cubical inches, therefore, at mean temperature and pressure, would weigh about 85 grains. It is very slightly soluble in water, but readily soluble in alcohol and ether, and in oils. It burns with a bright flame and much smoke, and when put into oxygen furnishes sufficient vapour to form a detonating mixture. Passed through a red-hot tube, it is resolved into carbon and carburetted hydrogen gas. Placed in the sunshine in chlorine, heat is evolved, hydrochloric acid formed, and a solid and liquid are produced, which appear to be compounds of chlorine, carbon, and hydrogen. Iodine does not act upon it, but dissolves it in small quantity, forming a crimson solution. Potassium exerts no action upon it at a temperature of 186° . Neither alkalis nor their carbonates act upon it. Nitric acid occasions in it little other change than the formation of a minute portion of hydrocyanic acid. Sulphuric acid added to it over mercury, exerted a moderate action; no heat was evolved, no blackening

took place, no sulphurous acid was formed, but the acid became of a light-yellow colour, and a portion of a clear colourless fluid floated, which appeared to be a product of the action, and which was not altered by water, and solidified at 34° , being then white and crystallized.

Mr. Faraday's attention was next directed to the *composition* of the substance: he decomposed it by passing its vapour over heated oxide of copper, by which it was resolved into carbonic acid and water; and a careful determination of their weights gave (as the mean of several experiments) 1 hydrogen and 11.576 carbon, as its components. Several other experiments led to the conclusion, that in this substance the carbon and the hydrogen are in the mutual ratio of 12 to 1. But on examining the volume of oxygen requisite for the combustion of this substance, it was found that 100 volumes of its vapour required 750 of oxygen, and that the result was water, and 600 volumes of carbonic acid; so that to form the water 150 volumes of oxygen must have combined with 300 of hydrogen, and the remaining 600 volumes must have united to 300 volumes of carbon vapour to form 600 of carbonic acid. Hence, as

300 cubic inches of carbon vapour weigh	Grains.
300 " hydrogen gas	76.2
100 " vapour of this bicarburet should weigh	82.6

we must accordingly conclude, that although the ratio of the carbon to the hydrogen, in this compound, is as 12 to 1, it, in fact, consists of

LIQUID HYDROCARBURET.—In examining the liquid remaining after the separation at 0° of the above crystalline solid, it was found to exhibit peculiarities which seem to identify it as a peculiar and definite compound; and from such experiments as were made upon it, it is extremely probable that it consists of one proportional of each of its components, but in what state of condensation has not been determined.

QUADRIHYDROCARBURET. ETHERINE. ($4\text{ car} + 4\text{ h.}$)—It has already been stated, that a portion of the original oil-gas liquor is *volatile at common temperatures*; at the heat of the hand it passes off in vapour, and

may be collected as a gas over mercury. It burns with a brilliant flame: its specific gravity to that of hydrogen is as 28 to 1; to that of common air as 1.963 to 1; and 100 cubic inches weigh 59.3 grains. It condenses into a liquid when cooled to 0°, and enclosed in this state in a tube of known capacity, and hermetically sealed, the bulk of a given weight of it at common temperatures was ascertained: this, compared with water, gave its specific gravity as 0.627 at 54°; so that among solids or liquids it is the lightest body known. It scarcely dissolves in water, but readily in alcohol, and the solution effervesces from the escape of vapour when water is added. It is abundantly condensed by sulphuric acid. One volume of the acid condenses above 100 volumes of the vapour, producing great heat, but no sulphurous acid. The solution is dark-coloured, has a peculiar odour, and evolves no gas upon dilution. By detonation with oxygen, it was found that 1 volume of the vapour required 6 volumes of oxygen for perfect combustion, giving rise to 4 volumes of carbonic acid. The remaining 2 volumes of oxygen must have combined with 4 of hydrogen to form water. Upon which view, 4 volumes or proportionals of hydrogen = 4, are combined with two volumes of gaseous carbon, or 4 proportionals (6×4) = 24, to form 1 volume of the vapour, the specific gravity of which, compared with hydrogen, would be 28, which is also its equivalent number; or if

200 cubic inches of carbon vapour weigh	50.8
400 " hydrogen gas "	8.4
100 " etherine vapour should weigh	59.2

which closely approximates to the experimental result, so that the volume of etherine and its components may be represented thus:

Carbon. 6		Carbon. 6		=	<div>Etherine. 28</div>
Carbon. 6		Carbon. 6			
Hydrogen. 1	Hydrogen. 1	Hydrogen. 1	Hydrogen. 1		

and it consists of

<hr/>	<hr/>	<hr/>	<hr/>	<hr/>	<hr/>	<hr/>
Etherine	1	28	100.00	1		1.960

CHLORIDE OF ETHERINE.—As the relative proportions of the elements in this compound are the same as in olefiant gas, it became interesting to ascertain whether chlorine had the same action upon it. Chlorine and the vapour were therefore mixed in an exhausted retort, heat was evolved, and a liquid resembling hydrochloride of carbon formed; but it could not be identified with it, inasmuch as it consisted of nearly equal volumes of the vapour and of chlorine; and, therefore, contained twice as much carbon and hydrogen. It was, therefore, treated with excess of chlorine in sunlight; hydrochloric acid was formed, and chlorine absorbed; a peculiar fluid was also formed, consisting of hydrogen, chlorine, and carbon, but no

chloride of carbon. It seems not improbable that a compound of etherine and chlorine corresponding with that of olefiant gas and chlorine (or as some have called it "the Dutch liquor,") may exist, and this would agree with Regnault's formula, $(4\text{ car} + 4\text{ h} + 2\text{ c.})$ The elements of this chloride of etherine would be perfectly consistent with those of a combination of hydrochloric acid, with chloride of acetyl; in which case etherine might be represented as a hydruret of acetyl, or as $(4\text{ car} + 3\text{ h}) + \text{h}$, which, when exposed to chlorine, absorbs 2 volumes or equivalents; so that a chloride of acetyl and hydrochloric acid are formed, giving rise to $(4\text{ car} + 3\text{ h} + \text{c}) + (\text{h} + \text{c.})$ In other words, etherine, losing an atom of hydrogen, becomes acetyl, and if that atom of hydrogen be replaced by an atom of chlorine, chloride of acetyl is formed; if the displaced atom of hydrogen also combine with an atom of chlorine, it produces an atom of hydrochloric acid, which, combined with the chloride of acetyl, produces the hydrochlorate of chloride of acetyl, the elements of which are those of a bichloride of etherine. Regnault further finds, that when the hydrochlorate of chloride of acetyl is subjected to the further action of a stream of chlorine, another atom of hydrogen is carried off as hydrochloric acid, and an atom of chlorine left in its place; thus $(4\text{ car} + 3\text{ h} + \text{c}) + (\text{h} + \text{c})$ becomes $(4\text{ car} + 2\text{ h} + 2\text{ c}) + (\text{h} + \text{c})$, and by the continuous action of chlorine the whole of the hydrogen is ultimately carried off as hydrochloric acid, and perchloride of carbon remains.

Mr. Faraday's researches, in reference to the various forms of hydrocarbon, established a new and important fact in chemistry, which is, that substances may exactly resemble each other in the relative proportions of their constituents, and yet, in consequence of peculiarities in their atomic arrangement, exhibit perfectly distinct physical and chemical properties, presenting, as already remarked, a curious and interesting modification of isomerism. Thus, in etherine and in olefiant gas, the carbon and hydrogen are in the ratio of 6 to 1; but, in the former, the elements are united in the proportion of 24 to 4, and in the latter of 12 to 2. It has been observed by Dr. Turner, that this peculiarity is explicable on the supposition that the ultimate elements of such compounds are differently disposed. "It is to be presumed that the smallest possible particle of olefiant gas contains 2 atoms of carbon, and 2 of hydrogen; and that, in like manner, an integrant particle of etherine contains 4 atoms of each element. Neither of these substances could, I conceive, be formed by the direct union of a single atom of carbon and a single atom of hydrogen. If a combination of the kind were to occur, a new compound, different from any known at present, would be the result."

In respect to the nomenclature applicable in such cases there is obviously much difficulty. The compound of 2 atoms of carbon and 2 of hydrogen might be called *bihydrocarbon*, but the designation *olefiant gas*, however objectionable, is still generally retained. For the compound of 4 atoms and 4, the term *quadrocarburetted hydrogen* has been proposed, but that would rather imply it to consist of 4 atoms of carbon and 1 of hydrogen, than of 4 and 4; the term *quadrihydrocarbon* or *quadrihydrocarburet* has, therefore, been substituted; but perhaps *etherine* is less objectionable, implying its existence as an hypothetical base of *ether*, under which we shall again have to advert to it.

TERHYDROCARBON. SUPEROLEFIANT GAS. ($3\text{car} + 3\text{h.}$)—It seems probable that a hydrocarbon, the vapour of which contains in 1 volume 3 atoms of hydrogen and 3 of carbon, is occasionally produced during the destructive distillation of oil; and Dr. Henry (*Phil. Trans.*, 1821, p. 156) adverts to such a compound, discovered in oil gas by Mr. Dalton. Dr. Thomson describes it under the name of *tritocarbonyhydrogen*, but till some definite mode of obtaining it has been pointed out, and its properties experimentally ascertained, its distinct existence must remain doubtful.

NAPHTHA. ($6\text{car} + 5\text{h.}$)—This term is generally applied to a peculiar liquid hydrocarbon, which is both a natural and artificial product. Natural naphtha is obtained in considerable quantity at Baku, near Derbent, on the north-west shore of the Caspian Sea. The soil is a clayey marl, and so impregnated with naphtha, that, when turned up to the depth of a few inches, it will inflame on the application of a lighted candle; in this soil pits are sunk, in which the naphtha collects in considerable quantities. The purest European naphtha comes from Monte Ciaro, near Piacenza, in Italy: this hill consists of horizontal beds of argillite, in which pits are sunk till the water comes in, upon the surface of which the naphtha oozes and collects, and is occasionally skimmed off. An inferior kind is produced at Monte Festino, near Modena, in the vicinity of which subterranean fires often break out. A similar liquid may be obtained by the distillation of *petroleum*, or mineral tar, a substance which will be described among Bitumens.

Under the name of *coal-oil*, or *coal-naphtha*, a product closely resembling the former is known in gas-works; it is one of the results of the destructive distillation of pit-coal, some of the varieties of which yield it in large quantities; it is extremely volatile, and therefore generally passes on with the gas to the remoter parts of the condensing-apparatus, and often collects in large quantities in the gas-meters and gasometer-tanks, and even in the first branches of the mains, from the syphons of which it is often drawn off. When it is purified by distillation it is a colourless limpid liquid.

The properties of naphtha differ somewhat according to the sources whence it is obtained, but when carefully rectified or purified by repeated distillation with water, it appears to possess the same leading characters and composition, whatever be its source: indeed, it is extremely probable that natural and artificial naphtha are of one and the same origin, the former being derived from volcanic, the latter from ordinary distillation. The specific gravity of the purest Persian and Italian naphtha, varies from $\cdot 750$ to $\cdot 760$. But of the coal naphtha, from $\cdot 820$ to $\cdot 860$. The odour of the former is strong, bituminous, but not disagreeable; that of the latter, penetrating and unpleasant. It does not congeal at 0° . Upon the approximation of a flaming body, naphtha takes fire and burns with a voluminous, and very sooty, and difficultly-extinguishable flame. It communicates odour to water and to common alcohol; it dissolves in absolute alcohol, and in ether, petroleum, and oils. Caustic potash forms an imperfect soapy compound with it. Sulphuric and nitric acid slowly modify and decompose it. When pure, it is not acted on by potassium or sodium, and is, therefore, used to preserve those metals from oxidation. The boiling-point of naphtha is variously stated. It generally begins to boil

at about 160° , and the thermometer gradually rises to about 200° , where it continues some time, and then again rises to above 300° . Dr. Thomson states the boiling point of Persian naphtha, to be 320° to 352° . The density of its vapour is about 2.8. It dissolves the greater number of the essential oils, and the resins, and a little phosphorus and sulphur, and corrodes cork; it is remarkable for its property of dissolving caoutchouc, which first swells up, and then gradually gelatinizes, when digested in it with the aid of a gentle heat: in this pulpy state it is used to render various articles of clothing *water-proof*; the goods are stretched out, and varnished over with it, and then their varnished sides are applied to each other, and made to adhere by powerful pressure, so as to form a compound fabric or texture: the manufacture is completed, and the solvent driven off, by exposure to a moderate heat. This important and well-known application of the solution of caoutchouc in naphtha, or coal-oil, was first suggested by Mr. Macintosh, of Glasgow. Among other sources of naphtha, or at least of a liquid hydrocarbon closely resembling it in all its leading properties, we may enumerate caoutchouc itself, which yields it by destructive distillation. (See *Caoutchouc*.) The ultimate composition of naphtha has been variously stated, probably from the difficulty of obtaining it in one definite state, but all analysts agree in representing it as a true hydrocarbon. According to Dumas, a definite compound, having all the characteristic properties of naphtha, is obtained by depriving *spirit of turpentine* of its oxygen, by the action of potassium, and then subjecting it to careful distillation. (*Ann. de Ch. et Ph.*, L. 238.) When the vapour of these hydrocarbons has the density of 2.87, one volume of it may be regarded as containing three volumes of carbon vapour, and five volumes of hydrogen, and as

300 cubic inches of carbon vapour weigh	Grains.
500 " hydrogen gas weigh	78.9
100 " naphtha vapour should weigh	10.6
	89.5

Hence naphtha, or a hydrocarbon so constituted, would consist of

	Atoms.			Vols.	Sp. Gr.

By subjecting coal-naphtha to the action of chlorine, Laurent (*Ann. de Ch. et Ph.*, Lxiii. 27) has obtained two acid compounds, to which he has given the names of *chlorophenismic* and *chlorophenesic acids*. The former is a white solid, constituted in its anhydrous state by ($^{12} \text{car} + 3 \text{h} + 2 \text{o} + 3 \text{c.}$) The latter is represented by ($^{12} \text{car} + 4 \text{h} + 2 \text{o} + 2 \text{c.}$)

NAPHTHALIN. ($10\text{ car} + 4\text{ h.}$)—This name was first given by Dr. Kid (*Phil. Trans.*, 1821, p. 209), to a concrete crystalline substance found among the products of the coal-gas manufacture; it may be obtained by subjecting coal-tar to distillation; it passes over after the naphtha or coal-oil: when any of the varieties of the tar are so distilled that their vapour may be exposed to a high temperature, more or less naphthalin is formed. I believe that I first pointed it out as a binary compound of carbon and hydrogen, in 1819. (*Quar. Journ.*, viii. 287.) It was afterwards examined by Mr. Chamberlain. (*Ann. of Philos.*, xix.) It is generally first obtained in translucent flakes of a red or brown colour. By slow sublimation with a portion of powdered charcoal, it may be obtained colourless, and nearly inodorous; but when heated, it exhales a peculiar faint odour, which has been compared to that of the flower of the narcissus. Its taste is slightly aromatic; it is heavier than water, unctuous to the touch, and slowly evaporates at common temperatures. It fuses at about 200° , and crystallizes as it cools; at 400° it boils and distils over, with little change. When inflamed, it throws off a singularly large quantity of black smoke, which diffuses itself in light films of carbon through the air. It is insoluble in cold, and very slightly soluble in boiling water; alcohol, ether, the oils, and naphtha, dissolve it abundantly. The alkalis have no action on naphthalin: when long boiled in nitric acid, it is slowly altered, and a part of the acid decomposed: hot hydrochloric acid dissolves it very sparingly; acetic and oxalic acids more copiously: sulphuric acid dissolves and combines with it.

The proportions of carbon and hydrogen which constitute naphthalin, were first determined by Faraday, and his results subsequently confirmed by Liebig, Wöhler, and Laurent. The specific gravity of its vapour is 4.49, or compared with hydrogen as 64 to 1, so that 100 cubic inches should weigh 135 grains; assuming therefore 100 volumes of it to consist of 500 of carbon vapour, and 400 of hydrogen,

	Grains.
500 cubic inches of carbon vapour	= 127.0
400 " hydrogen gas	= 8.5
100 " naphthalin vapour	= 135.5

Hence the atomic composition of naphthalin stands as follows:—

NAPHTHALIN AND CHLORINE. CHLORIDE OF NAPHTHALIN.—The mutual action of chlorine and naphthalin has been examined by M. Laurent (*Ann. de Chim. et Phys.*, lii. 275). When chlorine is passed over naphthalin, heat is evolved, hydrochloric acid formed, and a semifluid compound remains, consisting of a solid and liquid chloride; the latter may be removed by cold ether. The *solid chloride* is insoluble in water, sparingly soluble in hot alcohol, and more soluble in boiling ether, from which it separates on cooling in transparent rhomboids. It fuses at 320° and in close vessels boils and is decomposed; but when carefully heated in a current of air, it may be volatilized without decomposition. It is not readily acted on either by acids or alkalis.

The *liquid chloride*, obtained by the evaporation of its ethereal solution, is yellow; insoluble in, and heavier than water: it is soluble in alcohol and ether, and may be distilled without decomposition. Analysis shows, that both these compounds contain chlorine in combination with a hydrocarbon, differing in composition from naphthalin; hence the term chloride of *naphthalin* is not quite appropriately applied to it. The exact proportion of its components has not been ascertained with precision.

NAPHTHALIN AND NITRIC ACID.—Two compounds of nitric acid and naphthalin have also been described by Laurent (*Ann. de Ch. et Ph.*, lix. 381), which he has distinguished as *nitronaphthalase* and *nitronaphthalese*. By distilling nitronaphthalase with lime he obtained a solid yellow sublimate, which he considers as the basis of that compound, and which he has called *naphthalase*.

NAPHTHALIN AND SULPHURIC ACID. SULPHONAPHTHALIN. SULPHONAPHTHALIC ACID. ($20 \text{ CAR} + 8 \text{ H} + 2 \text{ S}'$).—The action of sulphuric acid on naphthalin has been investigated by Faraday (*Phil. Trans.*, 1826). He found that, like several other hydrocarbons, it combined with that acid, and produced a peculiar acid body, which he called *Sulphonaphthalic acid*. He obtained it pure, by the following process: Naphthaline was fused with half its weight of sulphuric acid, which, on cooling, formed a red crystalline compound, soluble in water; carbonate of baryta was added to its solution, by which sulphate and sulphonaphthalate of baryta were formed; the former insoluble, but the latter soluble; its solution was filtered off, and sulphuric acid added to it sufficient to precipitate the baryta. An aqueous solution of sulphonaphthalic acid was thus obtained, of a bitter acid taste, and powerfully reddening litmus: concentrated by evaporation it became brown, thick, and, ultimately, solid and very deliquescent. By renewed heat it melted and charred, but did not flame, and ultimately gave sulphuric and sulphurous acid vapours, and left charcoal. Another portion of the acid was evaporated under an exhausted receiver, including a vessel of sulphuric acid. In some hours it became a white soft solid, apparently dry, and after a longer period was hard and brittle. In this state it was deliquescent in the air, but might be preserved unaltered in a close vessel. Its taste was bitter, acid, and metallic: when heated to 212° it melted, and crystallized and solidified as it cooled: more highly heated, water passed off, and it assumed a red tint, becoming probably anhydrous; further heated, it became brown and black, and naphthaline, sulphurous acid, and charcoal

were evolved. This acid dissolves in water, alcohol, and oils. Its aqueous solution forms neutral salts with bases, all of which are soluble in water, most of them in alcohol, and all combustible, leaving sulphates or sulphurets, according to circumstances.

To determine the composition of this acid, and its equivalent number, its neutral salt with baryta was chiefly experimented upon: and the following appear to be the relative proportions of its elements:—

Baryta	1	77	27.0
Sulphuric acid	2	80	28.1
Carbon	20	120	42.1
Hydrogen	8	8	2.8
<hr/>			
Sulphonaphthalate of baryta 1		285	100.0

We have, therefore, the following composition of the sulphonaphthalic acid:—

Carbon	20	120	57.8
Hydrogen	8	8	3.8
Sulphuric acid	2	80	38.4
<hr/>			
Sulphonaphthalic acid	1	208	100.0

Of the two proportionals, therefore, of sulphuric acid, one is, as it were, saturated by the hydrocarbon, for it only combines with 77 of baryta, which will be found to be the equivalent of one proportional of that base. This curious property of hydrocarbon, indicating its capability of uniting to an acid, saturating it, and performing, as it were, the part of a basis, has been more extensively inquired into and illustrated by Mr. Hennell: his experiments relate chiefly to certain combinations concerned and developed in the formation of ether, under which article the details will be given.

PARANAPHTHALINE.—Under this term Dumas and Laurent (*Ann. de Chim. et Phys.*, L. 187) have described a hydrocarbon closely resembling naphthaline in all its essential properties, but yielding a vapour having the density of 6.78, whence they infer that it consists of 15 atoms of carbon and 4 of hydrogen. Paranaphthaline is less volatile than naphthaline, and, therefore, when coal-tar is distilled, it is among the latter of its products. According to Reichenbach (*POGGEND., Ann.*, xxviii. 484), paranaphthaline is a mixture of naphthaline and another definite hydrocarbon, which he terms *paraffine*, and which we shall describe amongst organic products.

IDRIALINE.—This term is applied by Dumas to a native hydrocarbon, found in the mercury-mine of Idria, in Carniola, and which appears to be very analogous to naphthaline: it is said to consist of 3 atoms of carbon and 1 of hydrogen. (*Ann. de Chim. et Phys.*, L. 193.)

GAS ILLUMINATION: COAL-GAS.—Mixtures of the hydrocarbons now described, and of some other gaseous compounds, are abundantly produced during the destructive distillation of coal and oil, and of a variety of other vegetable and animal substances; and the gases thus obtained are employed for the purposes of illumination, as economical substitutes for tallow, oil, &c. The destructive distillation of pit-coal is a process carried

on upon a very extensive scale in several public and many private establishments. The coal is placed in oblong cast-iron cylinders, or *retorts*, which are ranged in furnaces, to keep them at a red-heat, and all the volatile products are conveyed by a common tube into a *condensing vessel*, kept cold by immersion in water; and in which the water, tar, ammoniacal, and other condensible vapours, are retained: the gaseous products consist principally of varieties of carburetted hydrogen, with more or less sulphuretted hydrogen, and carbonic oxide, and acid: these are passed through or over hydrate of lime, or through a mixture of quicklime and water*, in vessels called *purifiers*, by which the sulphuretted hydrogen and carbonic acid gases are absorbed, and the carburetted hydrogen gases transmitted sufficiently pure for use into *gasometers*, whence the pipes issue for the supply of streets, houses, &c. The coke remaining in the retorts is of a very good quality†.

The specific gravity of purified coal-gas is liable to much variation: sometimes it falls below 0.450, and at others exceeds 0.650. These differences are partly referable to the nature of the coal, but chiefly to the manner in which the process of distillation is conducted, as to duration, and temperature: it has already been remarked, that when the varieties of hydrocarbon are passed through highly-heated tubes, they are more or less perfectly decomposed into carbon and hydrogen: hence the gas which is obtained at a high temperature, or which, after its formation, has been in contact with red-hot surfaces, is apt to be partly decomposed; it is thus increased in bulk, but diminished in specific gravity, and in illuminating power; hence, too, analysis detects in coal-gas, more or less

* Mr. Parker, of Liverpool (*Phil. Mag.* vol. iii. p. 292), has proposed to pass the gas, as it comes from the coal-retorts, through red-hot iron tubes, by which the contaminating gases and vapours are further decomposed, and the quantity of useful gas much increased. This suggestion, if it succeeded, would greatly diminish the quantity of tar; but as carburetted hydrogen is decomposed at a red heat, it would, probably, tend to diminish the illuminating power of the gas, though it would increase its quantity. The *purification* of coal-gas is a subject of the utmost importance, especially as relates to perfectly freeing it from sulphuretted hydrogen, which if present produces *sulphurous acid* during combustion, and is, therefore, highly noxious; in the case of the escape of unburnt gas, sulphuretted hydrogen is an equal evil; it is fetid and unwholesome, and it causes the immediate tarnishing of silver and other metals: its presence is fortunately very easily detected by a piece of paper moistened with a solution of sugar of lead, and no gas should be allowed to be burned, which *blackens* that test. Coal-gas, however, though free from sulphuretted hydrogen, occasionally pro-

duces a little sulphurous acid when burned, and in such cases I suspect the presence of the vapour of sulphuret of carbon. Ammonia or some ammoniacal compound is also often found in coal-gas even after it has been deprived of all sulphur: its presence is very injurious to copper tubes and brass stop-cocks. It has been proposed to free the gas from this contamination by passing it through dilute sulphuric acid, or through a solution of alum.

† The following is, I believe, a correct account of the manufacture of gas for London and the suburbs on the 1st of January, 1835. 30 gas-works employing a capital of 2,200,000*l.* and deriving a yearly rental of about 400,000*l.*, using annually about 112,000 tons of coal, which produce about 1000 millions cubic feet of gas. There are in these works about 130 gas-holders, the united contents of which exceed 3,500,000 cubic feet; they supply about 120,000 lamps. During the longest nights, about 4,910,000 cubic feet of gas are consumed each night, for the production of which about 550 tons of coals are daily carbonized.

uncombined hydrogen. The best kind of coal for distillation is that which contains most bitumen and least sulphur. The chaldron should yield about 12000 cubical feet of purified gas, of which each Argand's burner, equal to six wax-candles, may be considered as consuming from four to five cubical feet per hour.

OIL GAS.—Some years ago, Messrs. J. and P. Taylor invented an apparatus for the conversion of oil into gas. It consists of a furnace with a contorted iron tube containing fragments of brick or coke, passing through it, into which, when red-hot, the oil is suffered to drop; it is decomposed, and converted almost entirely into charcoal, which is deposited in the tube, and into a mixture of carburetted hydrogen gases and vapours, of which from two to three cubic feet may be regarded as equivalent to five or six of coal-gas, for the production of light. (*Quarterly Journal*, vol. viii.) The commonest whale-oil, or even pilchard-dregs, quite unfit for burning in the usual way, afford abundance of excellent gas, requiring no other purification than passing through a refrigerator, to free it of its more condensable vapours*. A gallon of whale-oil affords about 90 cubical feet of gas of an average specific gravity of 0.900, and an Argand burner, equal to seven candles, consumes a cubical foot and a half per hour. If its specific gravity exceed 0.900, it may be considered as containing too large a proportion of the heavier hydrocarbons, by which the bulk of the produce is much diminished, which are apt to condense in the pipes and gasometer, and which also occasion a fuliginous deposit during the consumption of the gas in ordinary burners.

RESIN GAS.—In consequence of the high and generally fluctuating price of oil, it became an important object to obtain a gas, of equal brilliancy and purity to that which it affords, from materials at once cheaper and less liable to fluctuations of value; and with this view, attempts were made to decompose resin, in the apparatus above described. For this purpose melted resin was substituted for the oil; but the exit-pipes, by which the gas flowed off, soon became choked with a thick bituminous substance, which stopped the process; and the product of gas was small, and of inferior quality. Mr. Daniell overcame this difficulty, by the invention of an apparatus, for which he obtained a patent. The exit-pipe of the oil-gas apparatus rose from the upper part of the retort, and was purposely carried to a considerable height, that the volatile oil, which was condensed during the process, might flow back and add to the product of gas by its decomposition. It was the return of the volatile oil from resin, which choked up the pipes when that substance was employed; and Mr. Daniell, observing this, led the exit-pipe from the *under* part of the retort into the hydraulic main, so that the return of any condensed vapour was rendered impossible. His mode of treating the resin is to dissolve, with the assistance of a gentle heat, about 8 lbs. in a gallon of the essential oil, which is plentifully formed during the decomposition of oil for making gas, or of resin itself. This solution is allowed to trickle into

* Mr. G. Lowe, of the Chartered Gas Company, informs me that the gas from oil and resin not unfrequently contains 10 per cent. of carbonic acid, the effect of which on the illuminating power of the gas must be very detrimental.

the heated retort half filled with coke. A small diaphragm, just behind the exit-pipe, and filling half the diameter of the retort, prevents any of the liquid flowing into the hydraulic main. When the process is properly conducted, about 1000 to 1200 cubic feet of gas are obtained from the cwt. of resin, and rather more than the original quantity of volatile oil is condensed, which is again employed for the solution. It is necessary to add a small quantity of lime to the essential oil, to neutralize a little acetic acid, which is formed during the process. The apparatus works perfectly free from all obstruction. The gas thus formed is equal in quality to oil-gas of 100 cubic feet to the gallon. Its average specific gravity is 0.850; it requires no purification; and its smell is rather resinous, and not nearly so offensive as that of either oil or coal-gas. Two cubic feet are equal in illuminating power to above five of the common coal-gas, and the expense of the material from which it is made, is not above one-third of the expense of oil. The sources of supply are as inexhaustible, and more generally distributed, than those of coal; and the forests of America, France, Spain, and Italy, yield the turpentine in quantities only limited by the demand. Many large towns in this country, in America, France, Holland, and the Netherlands, at one time adopted the use of this gas, but the late improvements in the production of coal-gas have I believe led to the abandonment both of it and of oil-gas. The elegance and simplicity, however, of the manufacture, and the comparatively small capital required for the erection of the works, may, in some situations, give it a preference.

COMPOSITION AND ANALYSIS OF THE GASES USED FOR ILLUMINATION.—

Dr. Henry's researches are the most important in reference to the philosophy of the art of gas-illumination (NICHOLSON'S *Journal*, 1805; *Phil. Trans.*, 1808 and 1821, and 1824), and much interesting matter connected with the subject will be found in an essay by Dr. Turner and Dr. Christison (*Edin. Phil. Jour.*, 1825). The treatises of Mr. Accum and of Mr. Peckston contain an account of the apparatus, with details as to its construction and expense, together with much useful practical information.

The analysis of a mixture of hydrogen with carbonic oxide, carbonic acid, and hydrocarbon, often requires to be performed in investigations relating to the gases used for illumination; it may be approximately effected as follows: A hundred measures of the gas are introduced into a graduated tube, and the carbonic acid absorbed by a solution of potassa; the remaining gas is then transferred to thrice its volume of chlorine of known purity, standing over water in a tube of about half an inch diameter, and carefully excluded from the solar rays; after 24 hours the hydrocarbons and the excess of chlorine will have been absorbed, especially after a little agitation, and the remaining gas, if it consist of carbonic oxide and hydrogen only, may be analyzed by detonation with oxygen in excess; the measure of carbonic acid formed being equal to that of the original carbonic oxide. This proceeding depends upon the non-formation of chlorocarbonic acid in a mixture of carbonic oxide and chlorine in the contact of water, and out of the direct agency of the solar rays. Such mixture I have kept several days, occasionally renewing the chlorine as it became absorbed by the water, and have not observed any diminution in the bulk of the carbonic

oxide. In these cases it is necessary to ascertain the purity of the chlorine by its absorption by water, and to take care that no hydrocarbon has escaped its action.

But in consequence of the presence of other compounds of carbon and hydrogen, and of those singular vapours discovered by Mr. Faraday, in coal, and especially in oil and resin gases, the accurate analysis of these complicated products becomes a problem of some difficulty. Dr. Henry's papers (in the *Phil. Trans.*, for the years 1818, 1820, and 1824, and in the *Annals of Phil.*, vol. xv.,) contain details upon the subject, which the student should carefully consult. The removal of the hydrocarburetted vapours from these gases may, as Mr. Faraday has shown (*Phil. Trans.*, 1825, page 461), be accurately effected by the agency of sulphuric acid: this also absorbs olefiant gas, but much less rapidly than the vaporous compounds; and if the gas under examination be diluted with three or four times its bulk of common air or of hydrogen, and excluded from the sunshine, the absorption of olefiant gas by the acid will be prevented. The hydrocarburetted vapours may also be removed by subjecting the gas to the action of olive-oil already saturated with olefiant gas.

As far as concerns the comparative value of different hydrocarburetted gases for the purpose of illumination, it seems evident, from Dr. Henry's experience, that, whatever be their source or composition, it may be most accurately determined by the quantity of oxygen required to saturate equal volumes. In other words, the illuminating powers of the different gases will be proportioned to the number of volumes of gaseous carbon condensed into one volume of the gas; and of these the oxygen consumed, and the carbonic acid produced, afford an accurate measure. (HENRY'S *Elements*, 1826, vol. i. 432.) "If 100 volumes, for instance, of one gas, require for perfect combustion 100 volumes of oxygen, and 100 volumes of another gas take 200 of oxygen, the value of the second will be double that of the first. Specific gravity, though a guide to a certain extent, is not a sufficient one; for the weight of a gas may be owing to a large proportion of carbonic oxide, which only gives out a very small quantity of light. Photometrical experiments also appear to me to require greater perfection in the instruments that have been invented for that purpose, before we can implicitly trust to results obtained by their means: but there can be no fallacy in the combustion of these gases by oxygen, if conducted with ordinary care, and especially if in each instance an average be taken of two or three trials, which need not occupy more than a few minutes. Nor can it admit of doubt, that, other circumstances being equal, the brilliancy of light evolved by the combustion of gases which are constituted of purely inflammable matter, will bear a proportion to their densities, perhaps even a greater proportion than one strictly arithmetical; because, while, by the combustion of denser gases, a higher temperature is produced, the cooling agencies remain the same. It is probable, therefore, that of two gases composed of the same ingredients, that which has a double density will afford somewhat more than a double quantity of light."

ECONOMY OF GAS-ILLUMINATION.—The economy of gas-illumination may be judged of by examining the value of the products of distillation

of a chaldron of coals, the average cost of which may be considered as 25s. It should afford—

	£	s.	d.
1½ chaldron of coke, at 13s.	0	16	3
24 gallons of tar, ammoniacal liquor, and other products, at 1d.	0	2	0
12000 cubic feet of gas, at 10s. per 1000 C. F.	6	0	0
	£6	18	3

These products are taken nearly at their lowest value, but they afford ample grounds for showing the advantage of gas-illumination, not merely for public purposes, but also in private establishments. It appears that where about one hundred lights are required, a coal-gas apparatus will be found profitable.

The cost of a lamp, fed by gas, and giving the light of seven candles, will be.	s.	d.
Of Argand's lamp, with spermaceti oil	0	0¾ per hour.
Mould-candles	0	3½
Wax-candles	1	2

The following Table by Dr. Ure shows the relative intensities of light afforded by the combustion of different candles:—

Number in a Pound.	Duration of a Candle.	Weight in Grains.	Consumption per Hour: Grains.	Proportion of Light.	Economy of Light.	Candles equal to 1 Argand.
10 mould	5h. 9m.	682	132	12¼	68	5·7
10 dip	4 36	672	150	13	65½	5·25
8 mould	6 31	856	132	10½	59½	6·6
6 ditto	7 2½	1160	163	14¾	66	5·
4 ditto	9 36	1787	186	20¼	80	3·5
Argand oil-flame	512	69·4	100	

A pint of the best sperm oil, weighing about 13 ounces, burns, in a well-trimmed Argand, about 10 hours*.

* The following answers to some questions put by the Committee of the Athenæum Club to Mr. Faraday, are so generally applicable, that I venture to introduce them here. "Q. What is the ratio of light of an oil and gas burner?—In an excellent Argand oil lamp, compared with a 15-hole gas burner, the light of the gas was to that of the oil as 21 to 13. Q. What is the ratio of heat?—In experiments made to determine the heat evolved for *equal quantities of light* from oil and gas burning brightly from Argand burners, the heat from the oil being 2, that from the gas was nearly 3. Q. Is either sulphurous or sulphuric acid formed by the combustion of coal-gas in the ordinary way?—A little sulphurous or sulphuric acid is generally formed from the combustion of coal-gas. If well-purified gas be used this product is rarely sensible: it is less sen-

sible as sulphuric than as sulphurous acid. Upon closely questioning persons who have declared they smelt the sulphur from gas, I have usually found they meant something else—generally the oppressive heat, or the dry sensation, or the smell of a little gas unburnt, none of which have anything to do with the sulphur product from gas. Q. From a gas light, properly regulated, does unburned gas escape?—I do not believe that any gas escapes unburnt from a gas light well regulated. It is far more likely that oil vapour should escape unconsumed from an oil burner than gas from a gas burner. Q. Will an oil or gas light soonest soil the ceiling of a room?—Neither oil nor gas ought to soil, or will soil, the ceiling of a room, if well regulated. Either will do so when badly regulated. I think, of the two, oil is most liable to do so; because of

CARBON AND NITROGEN. BICARBURET OF NITROGEN. CYANOGEN. PRUSSINE. ($2\text{car} + n$) or *Cy*, or NC_2 .—This gaseous compound was discovered in 1815, by Gay Lussac (*Ann. de Chim.*, xcv.), and termed *cyanogen* (from *κυανος*, blue, and *γενναω*, I generate), in consequence of its being essential to the formation of *Prussian blue*. It may be obtained from dry and pure crystals of *cyanuret of mercury*. This substance, when heated in a small glass tube to dull redness, becomes black, and a quantity of mercury passes over and condenses in the cold part of the tube: the gas which is at the same time evolved must be collected over mercury. Under a pressure of between three and four atmospheres at the temperature of 45° , Mr. Faraday condensed cyanogen into a limpid colourless liquid, of a specific gravity of about 0.9, and a refractive power rather less than that of water. When a tube containing it was opened, the expansion within appeared inconsiderable, and the liquid slowly evaporated, producing intense cold. It does not conduct electricity.

At common temperatures and pressures, cyanogen is a colourless gas, and has a penetrating and peculiar smell, somewhat resembling that of bitter almonds. When a lighted taper is dipped into it, it is immediately extinguished, but the gas takes fire and burns upon the surface, in

the changes which take place in the wick, in the temperature of the oil, &c., during burning, and which do not occur with a gas lamp properly regulated.

Q. What are the comparative effects of oil and gas lights on the quality of the air, light for light?—It is exceedingly difficult to ascertain, and, if ascertained, to describe correctly the effects of lights on air, so as to convey a just opinion of their influence; thus, their power of heating is of advantage and desirable up to a certain point, and above that point is unpleasant and disagreeable: but that point depends upon many other things as well as the lights, and, what is still more important, differs for different persons, so that it becomes impossible to please all. Gas light will heat air faster than oil light; it therefore at first does good quicker, and afterwards does harm quicker than oil. As to the proportionate deterioration of air by the oxygen abstracted, I think it probable that gas would, *light for light*, have the greatest effect; but I do not believe that effect would be sensible in either case. As to the deterioration of air by the sulphurous acid and unburnt gas thrown into the room, I think little of it. Q. What are the comparative qualities of the light from oil and gas?—When the oil was burning in its best manner, still it gave a much yellower flame than the gas; the whiteness of the gas flame is a necessary consequence of its higher temperature.

Q. Taking all the circumstances into consideration, what, in your opinion, is the cause of the oppressive feeling complained of in certain rooms in the Athenæum?—In my opinion the principal cause of complaint is of the following nature: a house has been built, and every endeavour made to render floors, ceilings, windows, walls, and doors, tight and close; the rooms in it are well warmed during the day, and are brought to such a temperature and state that the first person who enters is fully satisfied; from fifty to two hundred persons are then introduced, evolving both heat and effluvia; a number of powerful gas burners are next put into and continue in action; and when the injurious agency of these causes is continued for one, two, or three hours, complaints are made that the heat is oppressive, or the odour unpleasant. Things are arranged so as to produce a perfect effect under one set of circumstances, and then, changing the circumstances, the effect is expected to remain the same, though it must of necessity be different. The large room and the library are made quite warm enough by daylight, when there are only a few persons there: then they are lighted, many persons enter, and they must of course very soon expect an oppressive sensation. I have no hesitation in believing that the cause of these complaints might be removed by extending and adjusting the system of ventilation."

contact with air, with a beautiful and very characteristic purple flame. Its specific gravity to hydrogen is as 26 to 1; and to common air as 1·82 to 1; 100 cubic inches weigh 55·5 grains, (56·472 grains, TURNER; or at the temperature of 32°, 59·2023 grains, THOMSON.) It sustains a high temperature without decomposition. Water dissolves 4·5 volumes, and alcohol 23 volumes, of this gas. Sulphuric ether and oil of turpentine also absorb it. The aqueous solution reddens vegetable blues; and, according to Vauquelin (*Ann. de Ch. et Ph.*, Oct. 1818), is subject to spontaneous decomposition, being gradually converted into carbonic and hydrocyanic acids, ammonia, a peculiar acid, which he calls the *cyanic*, and a brown substance containing carbon: the ammonia saturates the acids, and the carbonaceous compound is deposited. These changes are referable to the mutual reaction of the elements of cyanogen upon those of water. According to Wöhler (*Ann. de Ch. et Ph.*, lxxiii. 73), the mutual action of cyanogen and water is attended by the production of cyanic acid and ammonia, which, by combination, generate *urea*.

Cyanogen may be analyzed by detonation with oxygen, or by passing it over red-hot oxide of copper. One volume, detonated over mercury, with two of oxygen, produces two volumes of carbonic acid and one of nitrogen: whence it appears that cyanogen consists of its own volume of nitrogen, combined with carbon sufficient to form two volumes of carbonic acid; or of equal volumes of nitrogen and gaseous carbon; and if so constituted, as

	Grains.
100 cubic inches of carbon vapour weigh	25·4
100 " nitrogen gas	30·1
100 " cyanogen vapour should weigh	55·5

Cyanogen, therefore, is constituted of

Iodine, sulphur, and phosphorus, may be sublimed in cyanogen without change; but when they are heated in contact with cyanuret of mercury, compounds of those bodies with cyanogen are the result. It also combines with the metals, and constitutes compounds which might be called *nitrocarburets*: they are usually called *cyanurets*, or *cyanides*. The cyanurets also combine with each other, and produce an extensive and curious class of salts which have been termed *double cyanurets*. As a salifying body, therefore, cyanogen may be compared to chlorine, iodine, &c., for it not only combines, as a simple body would do, with the metals, but also forms a hydracid with hydrogen; in some of its properties it bears an analogy to sulphur.

CARBURET OF NITROGEN.—I employ this term to designate the brown matter which remains in the retort after the preparation of cyanogen from cyanuret of mercury, and which, according to Mr. Johnston (*BREWSTER'S Journal*, Second Series, i. 75), is a solid compound of carbon and nitrogen, isomeric with cyanogen. The same compound is produced by the action of mercury on a saturated alcoholic solution of cyanogen, and is also probably formed by charring certain animal substances. It is soluble in the alkalis. Heated in the air it yields several definite compounds of carbon and nitrogen in succession, and ultimately leaves a residue containing 1 atom of carbon and 1 of nitrogen, so that the carbon gradually burns away, leaving the nitrogen fixed till a *protocarburet* is formed.

CYANOGEN AND OXYGEN.—According to Liebig and Wöhler, there are three distinct isomeric combinations of cyanogen and oxygen, which may be represented as follows:—

1. Cyanic acid . . . ($cy + o$)
2. Fulminic acid . . . ($2\ cy + 2\ o$)
3. Cyanuric acid . . . ($3\ cy + 3\ o$)

CYANIC ACID. ($2\ car. + n + o$) or ($cy + o$) or cy' .—The existence of an acid composed of cyanogen and oxygen, was first suspected by Vauquelin; but for our knowledge of its composition, and properties, we are indebted to Wöhler and Liebig. When cyanogen is passed into alkaline solutions it is absorbed, and a cyanuret and cyanate are formed, which, however, cannot be effectually separated, so that, in this respect, the action of cyanogen on the alkaline solution corresponds with that of chlorine and of iodine. But, according to Wöhler, a true cyanate of potassa may be obtained by exposing a mixture of black oxide of manganese and ferrocyanuret of potassium to a dull red heat, carefully avoiding too high a temperature, and boiling the resulting compound in spirit of wine of the specific gravity of 0.86. As the solution cools, tabular crystals of *cyanate of potassa* are deposited. (*Ann. de Ch. et Ph.*, xxvii. 196.) When these are dissolved in cold water the solution slowly decomposes, and, if boiled, carbonic acid and ammonia are produced, in consequence of the re-action of the elements present. Cyanic acid forms a soluble salt with baryta, but it occasions insoluble precipitates in solutions of lead, mercury, and silver, and these cyanates may be decomposed by diffusing them through water, and exposing them to the action of a current of sulphuretted hydrogen, not in excess. A sour pungent liquid, smelling like acetic

acid, is thus obtained, but it is very prone to decomposition, and in a few hours becomes converted into carbonate of ammonia. (LIEBIG, *Ann. de Ch. et Ph.*, xxxiii. 208.)

According to the analysis of Wöhler (*Ann. de Ch. et Ph.*, xx. and xxvii.), corroborated by the experiments of Liebig, anhydrous cyanic acid consists of

Carbon	2	12	35.2	Cyanogen	1	26	76.3
Nitrogen	1	14	41.1				
Oxygen	1	8	23.7	Oxygen	1	8	23.7
Cyanic acid	1	34	100.0		1	34	100.0

But the anhydrous acid is only known in combination with bases, or with water, as obtained above, or as afforded by the distillation of dry cyanuric acid; in this state it contains

		Liebig.			
Carbon	} Cyanogen	1	26	60.1	60.23
Nitrogen		1	8	18.6	18.71
Oxygen		1	9	21.3	21.06
Water					
Hydrate of cyanic acid, or }		1	43	100.0	100.00
Cyanate of water					

The facility of the conversion of an aqueous solution of cyanic acid into bicarbonate of ammonia, will be apparent on reference to their atomic composition, for 1 equivalent of cyanic acid with 3 of water, or $(2\text{ car} + n + o) + (3h + 3o)$, are equal to 1 equivalent of bicarbonate of ammonia $2(car + 2o) + (n + 3h)$: or, represented in abbreviated symbols, $cy' + 3q = (2car' + A.)$

CYANATE OF AMMONIA. ($A + cy'$).—There are two isomeric cyanates of ammonia. When ammonia and the vapour of hydrated cyanic acid are brought together they combine into a white flocculent and crystallized substance, which, according to Liebig (*Chimie Organique*, i. 126), contains more ammonia than corresponds with a neutral salt: it is, therefore, apparently a basic salt, but in its properties it agrees with the ordinary cyanates; heated with acids it effervesces, and with alkalis it disengages ammonia; but when gently heated, either in the dry state, or in solution, it gives out ammonia and becomes converted into *urea*, which will be described amongst organic products.

CYANATES.—The salts of the cyanic acid are distinguished by the peculiar results of the action of most other acids upon them. If an acid be added to a dry or a dissolved cyanate, effervescence soon ensues, attended by a strong odour of cyanic acid, and if hydrate of lime be then added ammonia is evolved, which it was impossible to detect in the original cyanate. The cyanates of the alkalis are soluble; all the others insoluble. All the soluble cyanates, excepting that of ammonia, are resolved into ammonia and carbonates, when boiled in aqueous solution.

FULMINIC ACID. $(2n + 4car + 2o)$ or $(2cy + 2o)$.—Under the articles *Mercury* and *Silver*, the process for preparing detonating compounds of those metals, by acting upon their nitric solutions by alcohol, is stated:

the experiments of Liebig, and Gay Lussac (*Ann. de Ch. et Ph.*, xxiv. and xxv.), lead to the inference, that in these combinations the metallic oxides are united to an acid containing the same elements, and in the same relative proportions, as the cyanic acid, to which, in that particular state of combination, the term *Fulminic Acid* has been applied; but the equivalent of the fulminic acid is double that of the cyanic, or = 68. According to Liebig, the results of the action of nitric acid upon alcohol, are hyponitrous acid on the one hand, and on the other, aldehyd, and formic, and oxalic acids. In the presence of oxide of mercury or oxide of silver, 2 atoms of hyponitrous acid and 1 atom of ether (the elements of which are contained in the alcohol) become converted into fulminic acid, which unites to the metallic oxide, as shown in the following equation:—

When the vapour of nitrous acid is passed into a saturated solution of nitrate of silver in alcohol, there is an immediate precipitation of fulminate of silver.

Fulminic acid has not been isolated from the bases with which it is combined; at the moment of its separation by a stronger acid it is resolved into hydrocyanic acid and other products.

If regarded as anhydrous, it consists of

Cyanogen	2	52	76.5	Liebig.
Oxygen	2	16	23.5	76.74
				23.26
Fulminic acid	1	68	100.0	100.00

FULMINATES.—Liebig represents these salts as containing either 2 atoms of fixed base (neutral fulminates) or 1 atom of fixed base and 1 atom of water; the latter have an acid reaction. The 2 atoms of fixed base may be represented by 2 atoms of the oxide of an easily reducible metal, or by 2 atoms of the oxides of two different metals, also easily reducible. Thus for example, 2 atoms of oxide of copper, 2 atoms of oxide of silver, 2 atoms of oxide of mercury, or 1 atom of oxide of copper and 1 atom of oxide of silver, may combine with 1 atom of fulminic acid, to form a neutral salt. The fulminates with an alkaline base include 1 atom of alkaline oxide and 1 atom of easily reducible oxide, as, for example, 1 atom of oxide of silver and 1 atom of potassa, baryta, strontia, or oxide of zinc. There are no fulminates of two alkaline bases. When a fulminate of the first class, containing 2 atoms of oxide of silver or of oxide of mercury, is treated by an alkali, only half the oxide is replaced by 1 atom of the alkali. This singular property seems to indicate an intimate relation between the oxygen of the acids and of the oxides with which they combine. (*Chimie Organique.*)

CYANURIC ACID. ($3Cy+3O$).—These elements are only known in combination with 3 atoms of water, or as ($3Cy+3O+3Q$). Scheele first described this acid under the name of *pyrouric acid*; Serullas afterwards obtained it by another process, and termed it *cyanic acid*. (*Ann. de Ch. et Ph.*, xxxviii.) Its real nature and properties were first ascertained by Liebig and Wöhler. When urea is heated beyond its fusing point, it

evolves ammonia and is converted into a gray substance: if this be dissolved in sulphuric acid, and nitric acid dropped in till the solution becomes colourless, and then added to an equal volume of water, crystals of pure cyanuric acid are deposited. Liebig obtained cyanuric acid from a substance which is produced by the decomposition of the sulphocyanuret of ammonium, and which he calls *Melam*. Dry melam is dissolved by a gentle heat in strong sulphuric acid, and then added to 20 parts of water: the mixture is kept near its boiling-point for several days, till it no longer gives a white precipitate with ammonia; it is then evaporated and crystallized. These crystals, which are rhombic prisms, are composed of 1 atom of the terhydrated cyanuric acid and 4 atoms of water; these they lose by exposure to air, and fall into a white powder, sparingly soluble in water, inodorous, and slightly reddening litmus. It dissolves without decomposition in the strong acids, but by long boiling is converted into carbonic acid and ammonia. The prismatic crystals of cyanuric acid, dried at a temperature of 212° , lose 4 atoms of water of crystallization, and retain 3 atoms of combined water; in this latter state of composition the acid may be obtained in flattened octoëdra, or oblique quadrilateral prisms, terminated by diëdral summits, by cooling its boiling saturated solution in nitric or hydrochloric acid. The following, therefore, is the composition of the anhydrous cyanuric acid, as it exists in combination with bases, and which cannot be isolated:—

Cyanogen	3	78	76·5
Oxygen	3	24	23·5
<hr/>			
Anhydrous cyanuric acid	1	102	100·0

The crystallized hydrate (cyanurate of water) consists of

Anhydrous acid . . .	1	102	79
Water (combined) . . .	3	27	21
<hr/>			
Hydrate of cyanuric acid	1	129	100

And the prismatic crystals contain

Hydrate of cyanuric acid	1	129	78·2
Water of crystallization	4	36	21·8
<hr/>			
Crystals of cyanuric acid	1	165	100·0

CYANURATE OF AMMONIA.—This salt crystallizes in shining white prisms, efflorescent, and losing ammonia when heated; dried in vacuo it contains the elements of 1 atom of anhydrous cyanuric acid, 1 atom of ammonia, and four atoms of water.

CYANURATES.—The cyanuric acid combines with 3 atoms of bases, which are represented by the 3 atoms of water in the hydrate of the cyanuric acid. This water is either wholly or partially replaced by metallic oxides. The alkaline oxides form two series of cyanurates; in the one, the salt contains 1 atom of anhydrous acid, 1 atom of basic oxide, and 2 atoms of basic water; in the other, 1 atom of acid, 2 atoms of oxide, and 1 of water (as in the corresponding phosphates). There are no salts constituted of 1 atom of acid with 3 of alkaline oxide. But the cyanurate of silver is anhydrous, and contains 3 atoms of oxide

of silver; so that the relative proportion of elements *per cent.* is the same in the *cyanate*, the *fulminate*, and the *cyanurate of silver*, but they differ in the mode of their constitution. All the cyanurates are decomposed by nitric and by hydrochloric acid. The cyanuric acid which crystallizes from a solution of a cyanurate so decomposed, contains no trace of the oxide with which it was combined. The salts with alkaline bases fuse when heated, and leave an alkaline cyanate, whilst cyanate of ammonia, hydrated cyanic acid, carbonic acid, and nitrogen, are evolved. (LIEBIG, *Chimie Organique*.)

CYAMELIDE. INSOLUBLE CYANURIC ACID.—The hydrate of cyanuric acid, when kept for some time, becomes hard and white (like porcelain). In this state it is insoluble in water, dilute acids, alcohol, and ether; it is dissolved and decomposed by caustic alkalis, into ammonia, and alkaline cyanates and cyanurates.

CYANOGEN AND CHLORINE. CYANURET OF CHLORINE. CHLOROCYANIC ACID. (*cy* + *c*).—Gay Lussac procured this compound by passing a current of chlorine through a solution of hydrocyanic acid in water, till the liquid discoloured a dilute solution of indigo in sulphuric acid. He then deprived it of excess of chlorine by agitation with mercury, and submitted it to careful distillation, by which an elastic fluid was evolved, consisting of a mixture of carbonic and chlorocyanic acids; and which, when condensed into water, furnishes a strong-smelling colourless solution, which reddens litmus. According to the statement of Liebig, when excess of chlorine is passed into the aqueous solution of hydrocyanic acid, chloride of cyanogen, hydrochloric acid, and free chlorine, are contained in the liquid. When gently heated the chloride of cyanogen is disengaged, and is obtained pure by passing it through a tube containing chloride of calcium. It is gaseous at common temperatures, has an insupportable and pungent odour, and when cooled to 0° crystallizes in long needles which fuse at 5° and boil at 10° , but under a pressure of about 4 atmospheres remain liquid at 70° . When kept in this state in tubes hermetically sealed it forms, according to Persoz, white crystals of a solid chloride of cyanogen, having the same composition as the following. Water dissolves 25, ether 50, and alcohol 100 volumes of the gas. It is decomposed by the alkalis. When moist cyanuret of mercury is exposed in chlorine to the action of solar rays, a heavy yellow liquid is formed, insoluble in water, and having the odour of chloride of cyanogen; the same substance appears to be formed by the action of chlorine on fulminate of silver.

It appears from the researches of Gay Lussac and Serullas (*Ann. de Ch. et Ph.*, xcv. 205), that 100 volumes of the gaseous cyanuret of chlorine consist of 50 volumes of cyanogen + 50 volumes of chlorine, the gases combining without a change of volume: accordingly, as

		Grains.
50	cubic inches of cyanogen weigh	27.7
50	" chlorine	38.0
100	" cyanuret of chlorine should weigh	65.7

and it is a compound of

SOLID CHLORIDE OF CYANOGEN.—When a mixture of dry chlorine and hydrocyanic acid is exposed to the sun's rays, hydrochloric acid and solid chloride of cyanogen are formed: the latter, when pure, is white and sublimates in acicular crystals; it has a penetrating odour resembling that of the excrement of mice; its taste is pungent; its specific gravity 1.32; it fuses at 284° , and sublimates at 374° . When digested in hot water, it is resolved into cyanuric and hydrochloric acids. It is soluble without decomposition in alcohol and ether. According to Bineau 1 volume of the vapour of this compound is constituted of 1.5 of chlorine, and 1.5 cyanogen, so that the 3 volumes are condensed into 1. It combines with ammonia. According to Liebig, this chloride corresponds to cyanuric acid, and is represented by the formula ($3C + 3Cy$).

CHLOROCYANATE OF AMMONIA.—One volume of chlorocyanic vapour and two volumes of ammonia condense with slight evolution of heat into white granular crystals, permanent in the air, and inodorous. This salt fuses when heated, and yields ammonia and hydrochlorate of ammonia, leaving a yellow residue, having the characters of *mellon*. (BINEAU, *Ann. de Ch. et Ph.*, LXVII. 237, and LXX. 255.)

CYANOGEN AND IODINE. CYANURET OF IODINE. ($Cy + i$).—This compound was first obtained by Davy (*Quarterly Journal*, i. 289), and afterwards more fully examined by Serullas. (*Ann. de Ch. et Ph.*, xxvii.) It may be obtained by heating in a platinum capsule a mixture of one part of iodine with two of pulverized bicyanuret of mercury; they soon react upon each other, and as soon as white fumes arise the capsule may be placed under a dry bell glass; the action goes on and a white flocculent product is formed. Mitscherlich obtains this compound by distilling the mixture of iodine and cyanuret of mercury with a little water, in a retort; it yields acicular crystals of an acrid taste, pungent odour, and exciting a flow of tears. It is very poisonous. It is heavier than sulphuric acid. It dissolves in water, and still more readily in alcohol, and the solutions do not redden litmus: alkaline solutions decompose it, forming iodates and hydrocyanates. It is instantly decomposed by solution of sulphurous acid; iodine is disengaged, and hydrocyanic evolved. Dry sulphurous acid gas does not act upon it. From the experiments of Serullas, it is probably composed of

Carbon	2 . . .	12 . . .	3.0	} Cyanogen 1 . . .	26 . . .	17.3
Nitrogen	1 . . .	14 . . .	9.3			
Iodine	1 . . .	126 . . .	82.7		1 . . .	126 . . . 82.7
	<hr/>	<hr/>	<hr/>		<hr/>	<hr/>
	1	152	100.0		1	152 100.0

According to Bineau the cyanuret of iodine forms a definite liquid compound with ammonia. (*Ann. de Ch. et Ph.*, LXVII. 235.)

CYANOGEN AND BROMINE. CYANURET OF BROMINE. ($cy + b$).—Two parts of dry bicianuret of mercury are put into a small tubulated retort, or into the bottom of a sealed tube plunged into a freezing mixture: one part of bromine is then added; a vivid action ensues, and so much heat is evolved, that if the temperature were not kept down the bromine would be volatilized; bromide of mercury and cyanuret of bromine are formed; the latter crystallizes in needles in the upper part of the tube, whence it may be sublimed into a cold receiver by the application of a gentle heat: sometimes it forms small cubic crystals. In many respects its physical properties resemble those of cyanuret of iodine; its odour is excessively pungent, and it is so volatile as to exist in vapour at temperatures above 60° . It is more soluble in water and alcohol than the compound of iodine. Solution of potassa transforms it into cyanate and bromide of potassium. The solution furnishes a precipitate when added to nitrate of silver, composed of cyanuret and bromide of silver, easily separable by ammonia, which dissolves the latter but not the former. Like the cyanuret of iodine, it is extremely deleterious to animals. One grain of it dissolved in a little water, and introduced into the œsophagus of a rabbit, occasioned instant death, as rapidly as hydrocyanic acid; it cannot, therefore, be examined without risk. Its composition has not been accurately determined. (SERULLAS, *Ann. de Ch. et Ph.*, vol. xxxiv. p. 100.) It combines with ammonia in two proportions, forming a solid and liquid compound. (BINEAU, *Ann. de Ch. et Ph.*, lxx. 257.)

CYANOGEN AND HYDROGEN. HYDROCYANIC ACID. CYANHYDRIC ACID. PRUSSIC ACID. ($cy + h$) or hcy or CyH .—This compound was first obtained by Scheele (*Stockholm Trans.*, 1782, 1783), and its composition ascertained by Berthollet in 1787, and by Clouet (*Ann. de Ch. et Ph.*, xi. 30). It was not, however, till the discovery of cyanogen by Gay Lussac, in 1815, that its real nature was understood, and its components accurately determined. Cyanogen and hydrogen have no tendency to direct combination, but by the action of certain acids on the metallic cyanurets, hydrocyanic acid is formed by double decomposition: in this way it is obtained by the action of hydrochloric acid on bicianuret of mercury, and the process is conducted as follows:—Introduce the cyanuret into a tubulated glass retort, and pour upon it rather less than its weight of hydrochloric acid (sp. gr. 1.20). Adapt a horizontal tube to the beak of the retort, about two feet long and half an inch diameter; fill the first third of the tube next the retort with small pieces of white marble, and the other two-thirds with fragments of fused chloride of calcium; adapt to its extremity a small receiver, surrounded by a freezing mixture; on applying a gentle heat to the retort, hydrocyanic vapour will pass through the tube, and become condensed in the cold receiver; any portion of hydrochloric acid and watery vapour that may arise along with it will be detained by the carbonate and chloride; after this part of the process the whole length of the tube should be gently heated, to expel the residuary hydrocyanic acid. As the extrication of carbonic acid from the marble is not only inconvenient, but liable to carry off hydrocyanic acid, the distillation of any portion of hydrochloric acid should, as far as possible, be prevented, by placing the retort in a horizontal position, using

the least possible quantity of it, and employing not more than a sufficient heat.

Another mode of obtaining hydrocyanic acid consists in placing cyanuret of mercury in a tube connected with a cooled receiver: sulphuretted hydrogen is then passed over the cyanuret, the sulphur of which combines with the mercury to form a sulphuret of mercury, and the hydrogen unites to the cyanogen to form hydrocyanic acid; the whole of which may be easily driven, by the application of a gentle heat, into the cold receiver, and there condensed. (VAUQUELIN.)

A third process for the production of anhydrous hydrocyanic acid is to distil by a gentle heat 15 parts of finely powdered ferrocyanuret of potassium, with a mixture of 9 parts of sulphuric acid and 9 of water: the product must be collected in a well-cooled receiver containing 5 parts of broken chloride of calcium: the distillation is stopped as soon as the chloride of calcium is covered by the liquid hydrocyanic acid, which is then carefully poured off and preserved in a well-stopped phial. (TRAUTWEIN.)

The hydrocyanic acid thus obtained is a limpid liquid of a strong pungent odour, very like that of bitter almonds, in which, and in other species of *amygdalus* and *prunus*, we shall afterwards recognise it. Its taste is acrid, and it is highly poisonous, so that the utmost care should be taken to avoid the inhalation of its vapour. It volatilizes so rapidly as to freeze itself, when a drop of it is placed upon a glass plate. Its specific gravity at 45° is 0.705, and at 64° 0.696; and the specific gravity of its vapour, as experimentally determined by Gay Lussac, is 0.9476: it boils at 80° , and congeals at 3 or 4° above 0° in its ordinary state, but when it is perfectly anhydrous it remains liquid according to Schultz at -40° . It burns with a bright flame. It scarcely affects the blue of litmus. It is liable to spontaneous decomposition, especially under the influence of light, becoming brown and evolving ammonia, changes which are prevented by the presence of minute portions of other acids. When water is present, the concentrated inorganic acids resolve it into ammonia and formic acid: 3 atoms of water and 2 of hydrocyanic acid, include the elements of 1 atom of formic acid and 1 of ammonia. It is resolved by chlorine into hydrochloric acid and chloride of cyanogen. The easily reducible oxides (of mercury and silver) decompose hydrocyanic acid, and yield water and a metallic cyanuret. When lime or baryta are heated to redness in hydrocyanic vapour, they afford cyanurets and cyanates, and hydrogen is evolved.

In the voltaic circuit hydrocyanic acid yields hydrogen at the negative, and cyanogen at the positive, electrode. When its vapour is mixed with oxygen, it may be burned by the electric spark, in which case two volumes of hydrocyanic vapour require for perfect combustion two volumes and a half of oxygen: the results are water, two volumes of carbonic acid, and one volume of nitrogen. When potassium is heated in the gas, cyanuret of potassium is formed, and hydrogen, equal to half the volume of the acid, liberated: it appears, therefore, that there is the strictest analogy between the hydrocyanic and the other hydracids, and that one volume of cyanogen and one of hydrogen form two volumes of the vapour hydrocyanic acid: and as

50 cubic inches of cyanogen weigh	Grains. 27·74
50 " hydrogen	1·06
<hr/>	
100 " hydrocyanic acid should weigh .	28·80

Hydrocyanic acid, therefore, is a compound of

						Vols.	Sp. Gr.
Carbon 2 . 12] . 44·5	} Cyanogen	1 . 26 . 96·3	0·5 . 0·91				
Nitrogen 1 . 14 . 51·8							
Hydrogen 1 . 1 . 3·7		Hydrogen 1 . 1 . 3·7	0·5 . 0·03				
<hr/>							
Hydrocyanic acid 1 . 27 . 100·0		1 . 27 . 100	1 . 0·94				

Hydrocyanic acid is used in medicine as a sedative, and several formulæ have been given for its preparation, so as at once to obtain it of a convenient strength for pharmaceutical purposes. The Pharmacopœia directs the decomposition of ferrocyanuret of potassium by dilute sulphuric acid, and the state of dilution of this hydrocyanic acid is such that it contains 2 per cent. of the real acid. (See *Ferrocyanuret of Potassium* and *Cyanuret of Silver*.)

The specific gravity of hydrocyanic acid when thus largely diluted cannot be resorted to as a criterion of its strength, hence other modes of determining this have been adopted. Dr. Ure recommends the following:—To 100 grains, or any other convenient quantity of the acid, contained in a small phial, add, in succession, small quantities of pure peroxide of mercury in very fine powder, till it ceases to be dissolved on agitation: the weight of the oxide taken up, being divided by 4, gives a quotient representing the quantity of real acid present. By weighing out beforehand, on a watch-glass, 40 or 50 grains of the peroxide, the residual weight of it shows at once the quantity expended. (*Quarterly Journal*, xiii. 312.) Dr. Ure's *Essay* also contains a table of the specific gravity of the acid of various degrees of dilution, and directions for detecting the presence of hydrochloric acid in it. The strength of the pharmaceutical hydrocyanic acid may also be determined by the weight of the precipitate obtained by nitrate of silver, (cyanuret of silver,) every 3 grains of which when well washed and dried, are equivalent to 1 grain of anhydrous hydrocyanic acid.

Another mode of obtaining dilute hydrocyanic acid is to pass sulphuretted hydrogen through water, holding in solution a known quantity of bicyanuret of mercury, so as completely to decompose it: the excess of sulphuretted hydrogen is then abstracted by carbonate of lead, and the solution of hydrocyanic acid filtered: but in this process it is difficult to obtain a perfectly clear and colourless solution without the addition of a drop or two of hydrochloric, or sulphuric acid.

A third process is that suggested by Mr. Clarke, of Glasgow. (THOMSON'S *System*, ii. 220.) In 100 drachms of water dissolve eight drachms and a quarter of *cyanuret of potassium*, and add to the solution eighteen drachms and a half of crystallized tartaric acid, previously dissolved in twenty drachms of water. A double decomposition takes place; bitartrate of potassa falls down, and about 120 drachms of water remain, holding in solution $3\frac{3}{8}$ drachms of hydrocyanic acid; or 2·81 per cent. of the solution is hydrocyanic acid. A little bitartrate of potassa

also remains, which may be avoided by using a little alcohol mixed with the water.

A fourth process recommended by Giese, (*TURNER'S Elements*.) is as follows: 20 drachms of ferrocyanuret of potassium are dissolved in 80 of water, and with the solution is mixed a dilute acid made previously with 18 drachms by weight of strong sulphuric acid, and 40 drachms of water, and allowed to cool. The dilute hydrocyanic acid is then distilled off, and if the amount is not 120 drachms, distilled water is added to make up that weight. This is nearly the process of our Pharmacopœia.

As hydrocyanic acid in its dilute state is liable to decomposition, it should be prepared in small quantities and preserved in well-stopped phials out of the presence of light: or a very minute addition of dilute sulphuric acid may be made to it, by which its tendency to change is prevented.

When dilute hydrocyanic is pure, it leaves no residue on evaporation: hydrochloric acid is detected in it by heating it in a water-bath so as to expel the hydrocyanic acid, and then testing by sulphate of silver: if sulphuric acid be present, it occasions a precipitate on adding nitrate of baryta, which is insoluble in nitric acid.

The virulently poisonous nature of this acid has led to its occasional administration with criminal intentions: the mode in which it produces death, and the symptoms, are enumerated by medical and physiological writers, but the chemist may be called upon to suggest means of detecting it: this is generally easily effected in consequence of its very peculiar odour; and if the fluid containing it be agitated with finely-powdered peroxide of mercury, crystals of cyanuret of mercury may be obtained on evaporation. The following is an accurate test of its presence, originally suggested by Scheele: to the suspected liquid add a solution of *protosulphate* of iron, and afterwards drop in pure potassa in slight excess, and after a short exposure to the air, redissolve the precipitate in hydrochloric acid. If hydrocyanic acid be present, the tint of Prussian blue will appear. Except in cases of recent examination it is not easily detected in the contents of the stomach after death, since it is decomposed with their putrefaction. In such cases Leuret and Lassaigne have recommended the following procedure: The stomach and its contents, cut into pieces, are carefully distilled with water slightly acidulated by sulphuric acid: the volatile products are condensed in a receiver surrounded by ice, and examined by the above-mentioned method: in such cases the acid is also generally recognised by its odour.

Ammonia, and chlorine, are the most effective antidotes in cases of poisoning by hydrocyanic acid; but for its toxicological history I must refer to writers on that subject. (*CHRISTISON, On Poisons. PEREIRA, Elem. of Mat. Med.*)

HYDROCYANATE OF AMMONIA. CYANURET OF AMMONIUM.—This salt may be obtained by mixing hydrocyanic acid with liquid ammonia; it is anhydrous, and crystallizes in cubes or small prisms, and is extremely volatile. Bineau obtained it by heating equivalents of cyanuret of mercury, or of dried ferrocyanuret of potassium, with hydrochlorate of ammonia. (*Ann. de Ch. et Ph.*, Lxvii. 231.) Dr. Thomson states, that

when Prussian blue is exposed to a red heat, and the products of its decomposition received over mercury, the glass receiver becomes coated with crystals of this salt. Hydrocyanate of ammonia soon suffers spontaneous change, and it is decomposed by carbonic and other feeble acids. From Bineau's experiments it appears to consist of 17 ammonia + 27 hydrocyanic acid, elements which upon the ammonium theory are equivalent to $(n + 4h) + cy$.

CYANOGEN AND SULPHUR. SULPHOCYANOGEN. CYANURET OF SULPHUR. $(cy + 2s)$.—Sir H. Davy obtained this compound in 1816, by heating a mixture of sulphur and bichcyanuret of mercury. (*Quart. Jour.*, i. 289.) Liebig obtains it by saturating a concentrated solution of sulphocyanuret of potassium with chlorine, or by boiling a soluble metallic sulphocyanuret in dilute nitric acid; it falls in the form of a yellow precipitate, which preserves its colour when dry, and is insoluble in water, alcohol, and ether, but soluble in hot sulphuric acid, from which it is again thrown down by water. It is decomposed by concentrated nitric acid: when heated with potassium, sulphuret, cyanuret, and sulphocyanuret of potassium are formed: subjected to dry distillation, it yields carburet of sulphur, and ultimately nitrogen and cyanogen. (LIEBIG.) By digesting cyanuret of mercury in chloride of sulphur, Lassaigne obtained a compound in brilliant crystals, which he regarded as containing 4 atoms of cyanogen and 1 of sulphur (*Ann. de Ch. et Ph.*, xxxix.), but which, according to Liebig, are a compound of chloride of cyanogen with chloride of sulphur.

CYANOGEN, SULPHUR, AND HYDROGEN.—By mixing cyanogen and sulphuretted hydrogen, Gay Lussac obtained a yellow crystallized compound. (*Ann. de Ch. et Ph.*, xcv.) This probably consists of one atom of cyanogen, and one of sulphuretted hydrogen, and is identical with the compound obtained by passing sulphuretted hydrogen into a saturated alcoholic solution of cyanogen. The mutual action, however, of cyanogen and sulphuretted hydrogen requires to be more minutely examined. We are indebted to Mr. Porrett (*Phil. Trans.*, 1814), for our knowledge of a triple compound of cyanogen, sulphur, and hydrogen, which he termed *sulphuretted chyazic acid*, but the term *sulphocyanic acid*, or *hydrosulphocyanic acid*, is now generally applied to it.

SULPHOCYANIC ACID. HYDROSULPHOCYANIC ACID. SULFOCYANHYDRIC ACID. $(cy + 2s + h)$.—This acid is obtained by decomposing basic sulphocyanuret of lead by dilute sulphuric acid, taking care to leave excess of lead, which is afterwards removed by sulphuretted hydrogen. It is also formed when sulphocyanuret of silver diffused through water is decomposed by sulphuretted hydrogen.

Hydrosulphocyanic acid is colourless, easily decomposed by exposure to

air or heat, yielding among other products a peculiar yellow insoluble powder: chlorine and nitric acid abstract its hydrogen, and evolve sulfo-cyanogen; by their prolonged action cyanic and sulphuric acids are formed, and ultimately ammonia. It reddens the solutions of persalts of iron; it is not poisonous; it exists in the seeds of the cruciferous plants, and in human saliva, and that of the sheep. From the experiments of Porrett (*Ann. of Phil.*, xiii.), confirmed by Berzelius, it consists of

SULPHOCYANURET OF AMMONIUM. HYDROSULPHOCYANATE OF AMMONIA. ($cy + 2s$) + ($n + 4h$) or ($cy + h + 2s$) + ($n + 3h$), obtained by saturating ammonia with hydrosulphocyanic acid, and evaporating in vacuo. It is also formed by the mutual action of sulphuret of carbon and alcohol saturated with ammonia. It is decomposed by heat.

CYANURET OF SELENIUM.—No binary compound of cyanogen and selenium has been obtained; but by fusing selenium with ferrocyanuret of potassium, a compound is formed analogous to that of sulphur: the *hydroseleniocyanic acid* has, however, not been separated, so that its existence is as yet hypothetical.

CARBON AND SULPHUR. BISULPHURET OF CARBON. ($car + 2s$) or CS_2 .—This compound was first obtained in 1796 by Lampadius, while distilling a mixture of pyrites and charcoal, and he termed it *alcohol of sulphur*. It was long regarded as a triple compound of carbon, sulphur, and hydrogen, till Clement and Desormes (*Ann. de Chim.*, xlii.), and Cluzel (*Ann. de Chim.*, lxxxiv.), showed the absence of hydrogen; its properties and composition were afterwards more accurately determined by Marcet and Berzelius (*Phil. Trans.*, 1813, p. 171). It is obtained by passing the vapour of sulphur over red-hot charcoal in a porcelain tube; or by distilling about six parts of yellow iron pyrites (bisulphuret of iron) with one of charcoal. The product should be conveyed by a glass tube into cold water. When purified by redistillation, at a low temperature, with chloride of calcium, it is transparent, colourless, and insoluble in water, but soluble in alcohol and ether; its refractive power in regard to light is very considerable. Its specific gravity is 1.272. It boils at 106° , and does not freeze at -60° . It is very volatile and inflammable, and has a pungent taste and peculiar fetid odour. The cold which it produces during evaporation is so intense, that by exposing a thermometer-bulb, covered with fine lint, and moistened with it, in the receiver of an air-pump, the temperature sunk, after exhaustion, to -80° . When a mercurial thermometer was used, the metal froze. Bisulphuret of carbon is soluble in fixed and volatile oils, and it dissolves camphor. It is decomposed, when water is present, by chlorine and iodine; and when potassium is heated in its vapour it burns and decomposes it. It

dissolves sulphur and phosphorus, and the solution often deposits those substances in beautiful crystals. Passed over heated lime or baryta, it produces ignition, and carbonates of those bases, together with sulphurets of calcium and of barium. It is also decomposed by copper and iron at a red heat. Nitrohydrochloric acid converts it into a crystalline compound hydrochloric, sulphurous, and carbonic acids. (BERZELIUS.)

A portion of this compound appears to be frequently formed during the production of inflammable gas from coal, and to be retained in the state of vapour by the gas after its purification by lime; such gas gives a sulphurous smell when burned, although perfectly cleansed from sulphuretted hydrogen, so as not to discolour carbonate of lead. (*Phil. Trans.*, 1820, p. 19.) When its vapour is burned with oxygen it forms carbonic and sulphurous acid. It consists of

		Berthollet, Thenard, Berzelius and Vauquelin.		Berzelius and Marcet.
Carbon	1	15.79	14	15.17
Sulphur	2	84.21	86	84.83
<hr/> Bisulphuret of carbon 1		<hr/> 38	<hr/> 100	<hr/> 100.00

According to Mitscherlich, (who has described a good form of apparatus for obtaining sulphuret of carbon upon a large scale, *Lehrbuch*, i. 153,) the specific gravity of the vapour of this compound is 2.670, and one volume of it is composed of one-third of a volume of sulphur vapour = $\frac{6.654}{3} = 2.218$, and half a volume of carbon vapour = $\frac{0.8438}{2} = 0.4219$.

CARBOSULPHURIC ACID. HYDROXANTHIC ACID.—According to Zeise, carbon and sulphur form a base acidifiable by hydrogen, which he has called *Xanthogene*, from the yellow colour of its compounds: the acid he terms *hydroxanthic acid*. When an alcoholic solution of pure potassa is mixed with bisulphuret of carbon, a compound is obtained, which, evaporated under the exhausted receiver of the air-pump over a surface of sulphuric acid, or exposed to a temperature of 32°, deposits acicular crystals, which become yellow by exposure to air, are very soluble, and from which, upon the addition of dilute hydrochloric or sulphuric acid, an oily-looking fluid, heavier than water, is separated, which is the *hydroxanthic acid*. Exposed to air it becomes covered with an opaque crust: it reddens litmus; tastes sour, astringent, and bitter; is inflammable; and at 212° is decomposed into bisulphuret of carbon and an inflammable gas. The action of ammonia on the sulphuret of carbon is very peculiar, and several new compounds result; but upon these subjects the reader must consult the original sources of information, which scarcely admit of abridgment, and are not very perspicuous in their details. (*Ann. de Ch. et Ph.*, xxi. and xxvi.; *Annals of Phil.*, N. S., iv.; *Quart. Journal*, xviii.)

According to Berzelius, the bisulphuret of carbon is a *sulphur acid*, and in combination with certain metallic sulphurets, or *sulphur bases*, forms a distinct class of *sulphur salts*. (See in reference to these compounds, COUERBE, *Ann. de Ch. et Ph.*, lxi. 25.)

CARBON AND PHOSPHORUS. PHOSPHURET OF CARBON.—To obtain this

compound, Dr. Thomson directs the following process (*System*, ii. 259):—Allow common phosphuret of lime to remain in water till it no longer evolves gas: then add to the liquid excess of hydrochloric acid, agitate for a few moments, and throw the whole upon a filter; phosphuret of carbon remains, which is to be washed and dried. This compound is a soft powder, of a yellowish colour, without taste or smell: exposed to air, it slowly imbibes moisture, and acquires an acid flavour. Exposed to a red heat, it burns, and gradually gives out its phosphorus, the charcoal being prevented burning by a coating of phosphoric acid. It consists of phosphorus 0.62 + carbon 0.38. (THOMSON'S *Annals*, viii. 157.) It would appear from the mode of obtaining this phosphuret, that it forms an ingredient in phosphuret of lime, as usually prepared; it also is obtained in the process for procuring phosphorus, and exists in the red matter which contaminates phosphorus when first distilled.

CARBON AND SELENIUM. CARBURET OF SELENIUM. SELENIURET OF CARBON.—Berzelius has announced the existence of this compound, but has not described its properties. (*Lehrbuch der Chemie*, Dresden, 1826.)

APPENDIX TO THE COMBINATIONS OF CARBON.

PRODUCTS OF THE DECOMPOSITION OF SULPHOCYANOGEN.—Under this head I shall notice several compounds which have been fully described by Liebig (*Chimie Organique*), but the theory and nomenclature of which will probably require future modifications.

MELLON.—When sulphocyanogen is heated to dull redness in a retort, it is resolved into sulphur, sulphuret of carbon, and a peculiar compound of carbon and nitrogen, to which, from its yellow colour, the above name has been given by its discoverer; it consists of 6 atoms of carbon and 4 of nitrogen, and if it be assumed that 4 atoms of sulphocyanogen $4(2\text{CAR} + n + 2\text{S})$ are decomposed, the result will be

4 atoms of sulphur	(4S)
2 „ bisulphuret of carbon	2(CAR + 2S)
1 „ mellon	(6CAR + 4n)

Mellon is a lemon yellow powder insoluble in water and in alcohol, and in dilute sulphuric and hydrochloric acids; it is dissolved, but decomposed by nitric acid and by the fixed alkalis. At a bright red or white heat, it is resolved into 3 volumes of cyanogen and 1 of nitrogen. It combines directly with potassium; light is evolved, and a *mellonuret of potassium* formed. With hydrogen it forms hydromellonic acid. When fused with iodide, bromide, and sulphocyanuret of potassium, it expels iodine, bromine, and sulphocyanogen, and produces mellonuret of potassium.

HYDROMELLONIC ACID ($6\text{CAR} + 4n + h$) is prepared by dissolving mellonuret of potassium in boiling water, and adding nitric, hydrochloric, or sulphuric acid; a white gelatinous precipitate is thrown down, which when dry is yellow, and is a hydrate of hydromellonic acid: it has a slightly acid reaction, and is not decomposed by hydrochloric or nitric acid.

CYANILIC ACID.—Mellon is decomposed by the continued action of boiling nitric acid; the action is attended by the disengagement of gas, and the solution deposits on evaporation colourless and anhydrous octoëdral crystals. On dissolving these crystals in boiling water, the solution yields pearly flakes on cooling, which retain a certain quantity of water. The acid is similar in composition to the cyanuric acid, with which it may be said to be isomeric; its formula according to Liebig being (when anhydrous) ($6\text{ cy} + 6\text{ o}$).

HYDROPER-SULPHOCYANIC ACID. ($\text{cy} + 3\text{ s} + \text{h}$.)—This compound is described by Liebig, (on the authority of Woskresensky,) as obtained by fusing sulphocyanuret of potassium in a stream of dry hydrochloric acid gas; hydrosulphocyanic acid is liberated and immediately decomposed into sulphuret of carbon, hydrocyanic acid, and a yellow product insoluble in water. If this operation be conducted in a retort, a quantity of the yellow product lines the neck of it; it is soluble in boiling alcohol, and precipitates on cooling in the form of a pale yellow crystalline powder sparingly soluble in water: it dissolves in the alkalis, and forms peculiar combinations with the other metallic oxides which are in general insoluble.

MELAM. ($13\text{ car} + 11\text{ n} + 9\text{ h}$.)—When sulphocyanuret of ammonium, or a mixture of 2 parts of sal-ammoniac and 1 of sulphocyanuret of potassium, are heated up to the fusing point of the latter, one solid and three volatile products are obtained; the latter are ammonia, sulphuretted hydrogen, and sulphuret of carbon; the solid body is melam, mixed with chloride of potassium, which may be removed by washing with water.

Melam is a whitish-gray powder, insoluble in water, alcohol, and ether. It is dissolved and decomposed by long boiling in solution of potassa. Boiling nitric and sulphuric acids dissolve it, and their solutions treated by alcohol produce a precipitate of *ammelide*; but if boiled for several hours, with the occasional addition of water, the melam is wholly transmuted into cyanuric acid and ammonia. Melam is soluble in dilute hydrochloric and nitric acid, and converted into *ammeline* and *melamine*; the same products are obtained by continued boiling in solution of caustic potassa. When fused with hydrate of potassa, it is transformed into cyanate of potassa and gaseous ammonia. By the action of heat it is resolved into mellon and ammonia.

To the above statement, Liebig adds the following explanatory equations:

The ultimate elements of 8 atoms
of sulphocyanuret of ammonium } $16\text{ car} \quad 16\text{ n} \quad 32\text{ h} \quad 16\text{ s}$
 $8(\text{cy} + 2\text{ s}) + (\text{n} + 4\text{ h})$ are

These are resolved by heat into

1 atom of melam	12 car	11 n	9 h	
5 " of ammonia		5 n	15 h

	16 car	16 n	32 h	16 s

And as regards the conversion of 1 atom of melam and 6 of hydrate of potassa into 6 atoms of cyanate of potassa and 5 of ammonia,

The ultimate elements of } 1 atom of melam are	12 <i>car</i>	11 <i>n</i>	9 <i>h</i>		
6 atoms of hydrate of potassa .			6 <i>h</i>	12 <i>o</i>	6 <i>po</i>
	13 <i>car</i>	11 <i>n</i>	15 <i>h</i>	12 <i>o</i>	6 <i>po</i>

Resolved by fusion into

6 atoms of cyanate of potassa .	12 <i>car</i>	6 <i>n</i>		12 <i>o</i>	6 <i>po</i>
5 „ ammonia		5 <i>n</i>	15 <i>h</i>		
	12 <i>car</i>	11 <i>n</i>	15 <i>h</i>	12 <i>o</i>	6 <i>po</i>

MELAMIN. ($6\text{ car} + 6\text{ n} + 6\text{ h}$.)—Liebig thus designates a salifiable base, produced as above stated by the action of alkalis and dilute acids on melam: it is one of the most highly azotised compounds with which we are acquainted. To obtain it, melam (procured by the distillation of a mixture of 1 part of sulphocyanuret of potassium, and 2 of sal-ammoniac, and washed to free it from chloride of potassium) is boiled in a solution of 1 part of hydrate of potassa in 20 of water, till the turbid liquor becomes clear; it is then evaporated by a gentle heat, till small brilliant crystals form in it, when it is set aside, and on cooling the whole of the melamin separates. It is purified by recrystallization.

Melamin forms anhydrous rhomboidal octoëdra, transparent and colourless, or slightly yellow: very sparingly soluble in cold water, and more soluble, but slowly so, in hot water. It is insoluble in alcohol and in ether. Its aqueous solution has a bitter taste, and is without action upon vegetable colours. Dry melamin fuses at a high temperature, and sublimes almost without decomposition; a small portion of it is, however, resolved into mellon and ammonia.

Concentrated nitric and sulphuric acids decompose melamin with the aid of heat into ammonia and ammelide, or ammeline. Fused with hydrate of potassa, the elements of 3 atoms of water combine with it, and transform it into 3 atoms of ammonia which escape, and 3 atoms of cyanic acid which remain in combination with the potassa.

The ultimate elements of } 1 atom of melamin are	6 <i>car</i>	6 <i>n</i>	6 <i>h</i>		
3 atoms of hydrate of potassa			3 <i>h</i>	6 <i>o</i>	3 <i>po</i>
	6 <i>car</i>	6 <i>n</i>	9 <i>h</i>	6 <i>o</i>	3 <i>po</i>

Resolved by fusion into

3 atoms of cyanate of potassa.	6 <i>car</i>	3 <i>n</i>		6 <i>o</i>	3 <i>po</i>
3 „ ammonia		3 <i>n</i>	9 <i>h</i>		
	6 <i>car</i>	6 <i>n</i>	9 <i>h</i>	6 <i>o</i>	3 <i>po</i>

Melamin combines with dilute acids to form crystallizable salts, all of which, except the double salts, have an acid reaction. The nitrate, phosphate, and oxalate, are less soluble than melamin; the acetate and

formiate are very soluble: it precipitates a part of magnesia from its solutions, and forms a double salt with the residue; in the same way it decomposes the salts of all the common metals. It combines directly with the anhydrous hydracids. All the salts of melamin with the oxyacids, contain an atom of water, like the corresponding salts of ammonia, and cannot exist without it. It forms double basic salts in which this atom of water is replaced by an equivalent of metallic oxide.

AMMELIN. ($6\text{ car} + 5\text{ n} + 5\text{ h} + 2\text{ o.}$)—A product of the decomposition of melam and melamin by acids and alkalis. When melamin is prepared by decomposing melam by a solution of caustic potassa, a liquor is obtained, which, after having deposited the whole of the melamin which it held in solution, still retains ammeline dissolved by the potassa, which is thrown down in the form of a white gelatinous precipitate by acetic acid. This precipitate is to be washed and re-dissolved in dilute nitric acid. This nitric solution yields, by evaporation, crystals of pure nitrate of ammeline. These crystals are again dissolved in dilute nitric acid, and from this solution carbonate of ammonia throws down perfectly pure ammeline, which may be washed and dried.

Ammeline may also be obtained by dissolving melam in weak and boiling hydrochloric acid; by evaporation crystals of hydrochlorate of ammeline and of melamin are obtained, which are to be re-dissolved in boiling water; from this solution ammeline is thrown down by caustic ammonia, and the remaining liquor yields crystals of hydrochlorate of melamin.

The precipitated ammeline forms brilliant white silky needles; it is insoluble in water, alcohol, and ether, but it dissolves in the caustic alkalis. Subjected to dry distillation, it affords a crystalline sublimate, ammonia, and a residue of pure mellon. With the acids it yields crystallizable salts. By the prolonged action of weak boiling acids, and of concentrated sulphuric acid, it is changed by the assumption of the elements of 1 atom of water: the products of this change are ammonia and ammeline. Fused with hydrate of potassa, it is transformed into ammonia and cyanate of potassa.

Ammeline is a very weak base, and only combines with the stronger acids, and never with the organic acids; its salts are crystalline, have an acid reaction, and are decomposed by water, which separates ammeline. On mixing nitrate of ammeline with the salts of many of the common metals, crystalline precipitates are formed, which are double basic salts, containing 1 atom of acid, 1 of ammeline, and 1 of metallic oxide. The oxyacid salts of ammeline contain, like the salts of ammonia, 1 atom of water: the double basic salts are anhydrous. Nitrate of ammeline crystallizes in large broad plates, or in long quadrangular prisms: it fuses when heated, and leaves ammeline as a residue, while nitric acid, and the products of the decomposition of nitrate of ammonia, are evolved.

AMMELID. ($12\text{ car} + 9\text{ n} + 9\text{ h} + 6\text{ o.}$)—A product of the decomposition of melam and ammeline by the concentrated acids: either of these is dissolved in concentrated sulphuric acid, the solution mixed with alcohol, and the precipitate formed washed with cold water till all traces of acid are removed. It is purified by dissolving it in dilute nitric acid,

and precipitating by carbonate of ammonia. Ammelid is a white powder, insoluble in water, alcohol, and ether; but soluble in alkalis and strong acids. With nitric acid it forms crystals which are decomposed by water. Exposed to the prolonged action of boiling dilute nitric or sulphuric acid, it is entirely resolved into ammonia and cyanuric acid. On adding slight excess of nitrate of silver to a boiling solution of ammelid in dilute nitric acid, and then ammonia till it forms a constant precipitate, white caseous flocculi are deposited on cooling, consisting of ammelid, in which the elements of an atom of water are replaced by those of oxide of silver.

THEORY OF THE COMPOSITION OF MELAMIN, AMMELIN, AND AMMELID.—In the following table Liebig attempts to explain the basic properties of melamin and ammelin, and the manner in which ammelid and cyanuric acid are derived from them. It is assumed that these substances contain the same radical as cyanuric acid, together with a combination of an equal number of atoms of nitrogen and hydrogen, which combinations we shall represent by m ; the formulæ will then stand as follows, $2m$ representing hn .

The cyanuric acid forms the beginning and end of the series. In melamin 6 atoms of oxygen are replaced by $6m$, and in ammelin 4 atoms by $4m$; both of these are saline bases; ammelid possesses no basic properties, and in it half the oxygen of the cyanuric acid is replaced by $3m$; lastly, when the whole of m is replaced by oxygen, the cyanuric acid again appears. The basic properties of these substances diminish, in proportion as the oxygen of the radical increases. Liebig says that the cyanuric acid may be compared to the phosphoric acid, and melamin to phosphuret of hydrogen, or to ammonia; inasmuch as ammonia and melamin combine directly with the hydracids; that is, without the intervention of water; but with the oxyacids an atom of water enters into the compound, where it plays the same part as in the salts of ammonia.

§ XII. BORON.

THIS substance was discovered in 1807, by Sir H. Davy, and in 1808 its properties were examined by Gay Lussac, and Thenard. (*Recherches Physico-Chimiques*.) It is obtained by heating in a copper tube two parts of potassium, with one of boracic acid previously fused and powdered. The fused matter is washed out of the tube with water, and the whole put upon a filter. The boron remains in the form of a brown insipid insoluble powder. According to Döbereiner (*Ann. de Ch. et Ph.*, ii. 214), one part of charcoal or lampblack, intensely heated in a gun-barrel, with nine parts of borax, previously fused, and in fine powder, produces a dis-

engagement of carbonic oxide, and a blackish mass results, which, after copious washings in boiling water, and once with hydrochloric acid, affords a greenish-black powder, having the characters of boron mixed with a little charcoal. The charcoal probably first reduces the soda, and the sodium decomposes the boracic acid; hence the produce of boron would probably be increased by adding to the borax half its weight of soda or potassa, and double the quantity of charcoal above-mentioned. According to Berzelius (*Ann. of Phil.*, xxx. 128), boron is most economically obtained by decomposing the borofluoride of potassium. This compound, dry and in powder, is heated in a porcelain crucible with potassium; the reduction goes on quietly, and the fused mass is triturated with water, by which the boron is separated, which is then washed upon a filter with a solution of hydrochlorate of ammonia, and afterwards with alcohol.

Boron is a very deep olive-coloured substance, infusible, inodorous, insipid, and a non-conductor of electricity. Its specific gravity exceeds 2. It is not acted upon by air, water, alcohol, ether, or oils. In the state of hydrate it long remains diffused through pure water, and passes through filters; but its precipitation is accelerated by saline solutions. It undergoes no change when heated in close vessels; but when nearly red-hot in the air, it takes fire and burns with difficulty into *boracic acid*. It is more easily oxidized by the action of nitric acid: the pure hydracids have no action upon it, but nitrohydrochloric acid converts it into boracic acid, and nitrohydrofluoric acid into fluoride of boron. At a high temperature it rapidly decomposes nitre, even with explosive violence; under the same circumstances, it also decomposes and deflagrates with the hydrate and carbonate of potassa: in the former case water is decomposed, and hydrogen evolved; in the latter, carbonic oxide is evolved in consequence of the decomposition of carbonic acid; in both cases borate of potassa is the result.

BORACIC ACID. (*bo + c o*) or *bo'*.—This, which is the only known compound of boron and oxygen, was first obtained by Homberg in 1702, and was used in medicine under the name of *sedative salt*. Its composition was demonstrated by Davy in 1807. It is usually obtained by dissolving the salt called *borax* in hot water, and subsequently adding half its weight of sulphuric acid; as the solution cools, white scaly crystals appear, which, when washed with cold water, are nearly tasteless, and which consist of boracic acid combined with about 40 per cent. of water, and retaining a little sulphuric acid, which it loses at a red heat; but inasmuch as such impure boracic acid attacks both metallic and porcelain crucibles, (for although neither sulphuric nor boracic acid separately injure platinum, the combination soon corrodes it,) this ignition cannot be effectually performed upon it, another method must be resorted to, which consists in decomposing a hot saturated solution of borax by hydrochloric acid; the hydrated boracic acid which falls as the liquid cools, may then be washed and dried, and safely heated in a platinum crucible, when it fuses into a hard transparent glass. Its specific gravity before fusion is 1.48; after fusion, about 1.8. At a white heat this acid slowly sublimes when exposed to air.

The *hydrated boracic acid*, is soluble in about 30 parts of cold, and 3 of boiling water: the latter solution deposits it in pearly scales as it cools: it is also soluble in alcohol, to the flame of which it communicates a green colour. It has little taste and feebly reddens vegetable blues; it renders turmeric brown, like an alkali. (FARADAY, *Quarterly Journal*, xi. 403.) The anhydrous acid becomes opaque when exposed to air; it is very fusible, and forms fusible combinations with many of the metallic oxides; hence, it is often used as a flux. When boracic acid is perfectly pure, it is deposited from its aqueous solution, not in scales, but in small prismatic crystals.

According to Davy, boron, when burned in oxygen, or acidified by nitric acid, combines with about 68 *per cent.* of oxygen; and with this, the theoretical estimate of Berzelius coincides: there is, however, a difference of opinion as to the equivalent of boron and that of the boracic acid; the analysis of Berzelius, Arfwedson, and Soubeiran, gives the proportion of the acid to that of the soda in *borate of soda* as 68 to 32, and assuming that salt as a compound of one equivalent of acid, and one of base, I have upon the authority of Gmelin, sanctioned by the above analysts, and by the composition of some of the other borates, adopted 68 as the equivalent of the *anhydrous boracic acid*; it will, therefore, consist of

					Berzelius	
Boron	. . .	1	. . .	20	. . .	29.41
Oxygen	. . .	6	. . .	48	. . .	70.59
						100.00
Boracic acid		1		68		100.00

And the *hydrated prismatic crystals* will consist of

					Berzelius.	
Anhydrous boracic acid	. . .	1	. . .	68	. . .	55.74
Water	„	6	. . .	54	. . .	44.26
						100
Hydrated boracic acid		1		122		100.00

These crystals lose 3 atoms of water when dried at 212°.

NATIVE BORACIC ACID, occurs among the volcanic products of the Lipari Islands, whence it has been collected for the manufacture of borax; it also exists in the hot springs of that district, and in those of Sasso, in the Florentine territory, whence the term *sassolin* applied to it by some mineralogists. It also occurs in *Datolite*, *Boracite*, and some other minerals, and in native *Borax*. An account of the Tuscan *lagoni*, whence large quantities of this acid are obtained, is given by Dumas (*Chim. App. aux Arts*, i. 379).

BORACIC ACID AND AMMONIA. BORATE OF AMMONIA. (A + 60'.)—According to L. Gmelin, a neutral borate of ammonia is obtained by dissolving boracic acid in slight excess of warm solution of ammonia; the temperature rises, and by slow cooling opaque rhombic octoëdra are deposited, which effloresce by exposure to air, and give off ammonia; they are soluble in 12 parts of cold water and the solution when heated is converted into *biborate*. This salt consists of

										100.00

BIBORATE OF AMMONIA. ($A + 2bo'$).—This salt is formed by saturating warm solution of ammonia by boracic acid, and slow evaporation: it yields transparent, irregular, six-sided prisms, at first tasteless, then hot and bitter, and having alkaline reaction on test paper. It dissolves in eight parts of cold water, and gives out ammonia when heated. L. Gmelin (*Handbuch*), Soubeiran (*Jour. de Pharm.*, xi. 34), Arfwedson (POGGEND., ii. 130). This salt contains

				Arfwedson.	L. Gmelin.

Biborate of ammonia	1	216	100.00	100.0	100.0

CHLORIDE OF BORON. ($bo + ^6c$).—Sir H. Davy first observed the combustion of boron in chlorine, and afterwards Berzelius found that on passing dry chlorine over heated boron, or over a red-hot mixture of dry boracic acid and charcoal, a permanent gas was formed which might be freed from chlorine by passing it through mercury. This gas has a pungent odour; it is colourless, fumes in contact of air, is rapidly absorbed by water, soluble in alcohol, and forms a liquid compound with ammonia. (*Ann. of Phil.*, xxvi. 129.) Its specific gravity according to Dumas is 3.942. When absorbed by water it forms boracic and hydrochloric acid.

It consists of

				Dumas.
Boron	1	20	8.5	9.29
Chlorine	6	216	91.5	90.71
Chloride of boron	1	236	100.0	100.00

IODIDE and BROMIDE OF BORON are unknown.

FLUORIDE OF BORON. FLUOBORIC ACID. ($bo + ^6f$).—In the hope of obtaining anhydrous fluoric acid, Gay Lussac and Thenard heated a mixture of vitrified boracic acid and fluor-spar; the result was not as they had anticipated, but a peculiar gaseous compound was obtained, to which they gave the name of *fluoboric acid*. (*Mem. d'Arcueil*, ii. 317.) Dr. John Davy obtained the same gas, not, however, perfectly pure, by heating in a glass retort, over a lamp, a mixture of one part of vitrified boracic acid, two parts of finely-powdered fluor-spar (fluoride of calcium), and twelve parts of sulphuric acid. (*Phil. Trans.*, 1812.) It is most probable that, in obtaining this gas, the oxygen of the boracic acid combines with the calcium of the fluor-spar to form oxide of calcium or lime, and that the boron and fluorine unite to produce the gas.

Fluoboric gas, according to Dr. Davy, has a specific gravity = 2.371, according to Dumas = 2.31; it is colourless, of a pungent odour, highly deleterious to respiration, and extinguishes flame. It strongly reddens litmus; and when bubbles of it are allowed to escape into the air, they produce a remarkable dense and white fume, in consequence of their eager attraction for, and combination with, aerial moisture. Water takes up 700 times its volume of the gas, increasing in volume and density, and forming a caustic and fuming solution, in which Berzelius found boracic and hydrofluoric acids in combination, (*borohydrofluoric acid*;) it would seem, therefore, that fluoboric gas decomposes water, and that the hydrogen of the water unites to the fluorine to form hydrofluoric acid,

and the oxygen to the boron, to form boracic acid. When the solution is concentrated, the hydrofluoric and boracic acids again decompose each other, and the original compound is reproduced. Neither the gas nor the liquid acid act upon glass, but they speedily decompose almost all organic substances: a piece of paper introduced into the gas, standing in a tall jar, over mercury, causes its rapid absorption, and becomes charred as if burned, in consequence of the abstraction of the elements of water. When potassium is heated in fluoboric gas, it burns, and a brown compound results, consisting of boron and fluoride of potassium: the latter may be dissolved in water, and pure boron remains. Regarding fluoboric gas as a binary compound, it consists of

				Berzelius.	Vols.	Sp. Gr.
Boron	1	20	16	16.24	1	1.3866
Fluorine	6	108	84	83.76	3	7.7572
	<u>1</u>	<u>128</u>	<u>100</u>	<u>100.00</u>	<u>4*</u>	<u>2.2809</u>

FLUOBORATE OF AMMONIA.—Fluoboric acid and ammonia condense each other apparently in three proportions. If *one* measure of the acid gas be admitted to *one* of ammonia, in a jar over mercury, complete condensation ensues, and a solid compound results, which sublimes without decomposition when gently heated. It consists probably of

				J. Davy.
Ammonia	2	34	21	20
Fluoboron	1	128	79	80
	<u>1</u>	<u>162</u>	<u>100</u>	<u>100</u>

LIQUID SUBFLUOBORATE OF AMMONIA.—*One* measure of fluoboric gas with *two* of ammoniacal gas, condensed each other into a colourless liquid, which, when heated, or exposed to air, lost ammonia, and became converted into the former solid. This liquid compound consists therefore of

				J. Davy.
Ammonia	4	68	34.69	33
Fluoboron	1	128	65.31	67
	<u>1</u>	<u>196</u>	<u>100.00</u>	<u>100</u>

Dr. Davy also found that a compound might be formed of 1 volume of fluoboric gas, and 3 of ammoniacal gas, or of 1 proportional of the former, and 6 of the latter, and which, in its chemical properties, closely resembled the preceding.

SULPHURET OF BORON.—When boron is strongly heated in sulphur-vapour, it burns and produces an opaque white compound, which by the contact of water yields boracic acid and sulphuretted hydrogen. (BERZELIUS.)

* In this calculated result, which nearly coincides with experiment, it is assumed that the specific gravity of boron vapour is 20 times that of hydrogen, and that the volume of fluorine which represents its specific gravity in reference to hydrogen is, as is the case with oxygen, equal to two equivalents.

SUCH are the general properties of the simple non-metallic substances, and of their mutual combinations; they have been described in the order suggested at page 350, and I trust that the principles of nomenclature which are there adverted to will now be intelligible, and that the arrangement, adopted in respect to them and their numerous compounds, will be thought sufficiently perspicuous and convenient to justify the application of a similar method to the *metals*, and to the multifarious combinations which that important class of substances form with the bodies which have been described in this chapter. I have already observed, that, strictly speaking, the basis of Silica, under the name of *silicon*, should have been placed among the non-metallic elements, and that the analogies which it bears to *boron* are such, as to justify its dismissal from the metals: but others of its characters have been but imperfectly examined; and, if general analogies are made the basis of our arrangements, it would not be difficult to show that, in many other cases, the line of demarcation between the non-metallic and metallic bodies, is so indistinct, as to render it probable that they may gradually merge into each other, and that the distinctive characters by which it has been attempted to separate them, are not well-founded: these matters will be more evident, when the history of the individual metals is examined; thus, the striking analogy that subsists between sulphur and arsenic, is such, as closely to approximate those substances; and some of the other acidifiable metals are, by a similar analogy, related to arsenic; and, on the other hand, carbon approximates so closely in certain of its characters, to those considered appropriate to the metals, as, in the opinion of some, to justify its being placed among them: in short, the more we examine into the details of our artificial arrangements, the less consistent do we in general find them with nature; so that they should always be regarded as merely tending to the convenience of description and discussion, and not as possessing any further claims upon our consideration. Hence, I have not thought it worth adverting, in detail, to the opinions of contemporary writers upon this subject, or enumerating the grounds upon which they have contrived plausibly to arrange the subjects of chemistry in an order extremely at variance with that which is here adopted. To describe those substances first, which, in the common acceptance of the term, are most important, which are of most frequent occurrence, and most influential in the majority of chemical phenomena, and to associate the description of compounds with those of their elements, seems to me to be the system which least perplexes the student, and is, therefore, that upon which the preceding and succeeding portions of this work are founded.

CHAPTER VI.

OF THE METALS, AND THEIR COMBINATIONS.

THE metals constitute a numerous and important class of simple substances. They are forty-three in number, and are enumerated in the following table with their equivalent numbers and symbols annexed.

	Equiv.	Symbol.		Equiv.	Symbol.
1. Gold	200	<i>aur.</i>	23. Palladium	54	<i>pal.</i>
2. Silver	108	<i>ag.</i>	24. Rhodium	52	<i>rh.</i>
3. Copper	32	<i>cu.</i>	25. Iridium	96	<i>ir.</i>
4. Iron	28	<i>fe.</i>	26. Osmium	100	<i>os.</i>
5. Mercury	200	<i>hg.</i>	27. Cerium	48	<i>ce.</i>
6. Tin	58	<i>sta.</i>	28. Potassium	40	<i>po.</i>
7. Lead	104	<i>pl.</i>	29. Sodium	24	<i>so.</i>
8. Zinc	32	<i>zn.</i>	30. Lithium	8	<i>li.</i>
9. Bismuth	72	<i>bi.</i>	31. Barium	69	<i>ba.</i>
10. Antimony	65	<i>an.</i>	32. Calcium	20	<i>cal.</i>
11. Arsenic	38	<i>ar.</i>	33. Strontium	44	<i>str.</i>
12. Cobalt	30	<i>cob.</i>	34. Magnesium	12	<i>mag.</i>
13. Platinum	99	<i>pla.</i>	35. Silicium	8	<i>si.</i>
14. Nickel	28	<i>nic.</i>	36. Alumium	26	<i>al.</i>
15. Manganese	28	<i>man.</i>	37. Yttrium	32	<i>yt.</i>
16. Tungsten	100	<i>tu.</i>	38. Glucinum	18	<i>gl.</i>
17. Tellurium	32	<i>tel.</i>	39. Zirconium	22	<i>zir.</i>
18. Molybdenum	48	<i>mol.</i>	40. Cadmium	56	<i>cad.</i>
19. Uranium	217	<i>urnm.</i>	41. Thorium	60	<i>th.</i>
20. Titanium	24	<i>ti.</i>	42. Vanadium	68	<i>va.</i>
21. Chromium	28	<i>chr.</i>	43. Lantium	?	<i>lan.</i>
22. Columbium	185	<i>col.</i>			

Of these metals the first seven were known in very remote ages. The ancients designated them by the names of the planets, to which they were supposed to have some mysterious relation; and each was denoted by a particular symbol, representing both the metal and the planet. (In respect to the origin and application of these symbols, see BECKMANN'S *History of Inventions*.)

Gold	was the Sun,	and was thus represented	☉
Silver	... Moon	...	☾
Mercury	... Mercury	...	☿
Copper	... Venus	...	♀
Iron	... Mars	...	♂
Tin	... Jupiter	...	♃
Lead	... Saturn	...	♄

Zinc was not known to the ancients, though they were probably acquainted with its ores, and with their property of forming brass when

fused with copper. (PLINY, lib. xxxiv., cap. 2 and 10.) The word *Zinc* first occurs in the writings of Paracelsus, who died in 1541. Bismuth is mentioned in the *Bermannus* of Agricola, written about 1530. Antimony was first obtained in its pure state by Basil Valentine towards the end of the fifteenth century; it is described in his *Currus Triumphalis Antimonii*. Arsenic and Cobalt were discovered by Brandt in 1733 (*Acta Upsal.* 1733 and 1742); the ores were known at a much earlier period. Platinum was first recognised as a peculiar body in 1741, by Mr. Charles Wood, Assay-Master in Jamaica (*Phil. Trans.*, vol. xlv.) In 1751, the distinctive characters of Nickel were shown by Cronstedt (*Stockholm Transactions*), and Manganese was obtained by Gahn in 1774 (BERGMAN'S *Opuscula*, vol. ii.) Tungsten was discovered by MM. Delhuyart, in 1781 (*Mémoires de Toulouse*). Tellurium and Molybdenum by Müller and Hielm, in 1782 (CRELL'S *Annals*, 1790 and 1798). Uranium by Klaproth in 1789. Titanium by Gregor, in 1789 (*Jour. de Phys.*, xxxix.) Chromium by Vauquelin, in 1797 (*Ann. de Ch.*, vol. xxv.) In 1802, Hatchet discovered Columbium (*Phil. Trans.*) Palladium and Rhodium were discovered by Wollaston; and Iridium and Osmium by Tennant, all in 1803 (*Phil. Trans.*) Cerium was announced in 1804, by Hisinger and Berzelius (GEHLEN'S *Journal*, ii.) Potassium and Sodium were discovered in 1807, by Davy, whose experiments also led to the discovery of the metallic nature of the ten following bodies (*Phil. Trans.*) Stromeyer discovered Cadmium in 1818 (*Ann. of Phil.*, xiii.) Thorium was discovered by Berzelius in 1829 (POGGEND., *Ann.*, xvi.), Vanadium by Sefström in 1830 (*Ann. de Ch. et Ph.*, xlvi.), and Lanthanum by Mosander in 1838.

Metals are chiefly found in the earth in *veins* which traverse the granitic, schistose, and limestone rocks; they also occur, although comparatively rarely, in rounded and detached fragments and nodules, disseminated through certain alluvial and diluvial strata. They seldom occur in an uncombined state, but almost always united to other substances, as in the following classes:—

i. *Native Metals* are those which occur pure or alloyed, such as platinum, rhodium, iridium, osmium, gold, silver, mercury, copper, antimony, arsenic, and tellurium.

ii. *Metals combined with simple non-metallic substances.* The compounds belonging to this class are the *native metallic oxides*, and *native chlorides*; *iodides* and *bromides* are extremely rare; and there are few *fluorides*. The *native metallic sulphurets* are a numerous and important series of ores. The *seleniurets* are rare. There are no native carburets, hydrurets, phosphurets, nor borurets.

iii. *Metals in combination with acids; Metallic Salts.* Of these the most common are the *native carbonates*, *sulphates*, and *phosphates*: there are a few *native borates*; and a few species belong also to this class in which the oxide is united to a *metallic acid*: such as the *native arseniates*, *chromates*, *tungstates*, *molybdates*, and *vanadates*.

PROPERTIES OF THE METALS.—*Opacity, &c.* The metals, as a class, are characterized by *opacity*, and a peculiar *lustre*. Their *opacity* is such, that even when extended into very thin leaves, they generally trans-

mit no light; silver-leaf, only one one-hundred-thousandth of an inch in thickness, is perfectly opaque. Gold, however, when beaten out into leaves one two-hundred-thousandth of an inch in thickness, transmits green rays of light; and it is probable that thin films of other metals transmit certain rays of light. Their lustre depends upon their great power of reflecting light, in consequence of their opacity. They are excellent conductors of heat and of electricity. (See pages 155 and 245.)

The polished metals are very imperfect radiators and receivers of heat (page 211); but they are excellent reflectors both of light and heat, and hence their peculiar fitness for the construction of mirrors.

Whenever the polish of the metallic surface is impaired, its power of reflecting heat suffers a proportionate diminution, while its power of absorbing, and also of radiating heat, is proportionably increased. (See page 206.)

Crystallization. The greater number of the metals are susceptible of assuming the crystalline form. With many this may be effected by fusion and slow cooling, and especially by suffering a ladle, or crucible, filled with the melted metal, to concrete externally, and then perforating the solid crust, and pouring out the liquid interior; the cavity so formed will then be lined with crystals: this mode of proceeding answers extremely well with bismuth, which furnishes a singular congeries of cubic crystals (p. 113). When the metals are precipitated by each other, they often crystallize during their deposition, as is seen in the precipitation of silver by mercury, and in that of lead by zinc. A stick of phosphorus immersed in a solution of silver becomes incrustated with beautiful metallic crystals, which, after some time, perfectly encase the phosphorus. Gold is occasionally deposited in a crystalline form, from its ethereal solutions. Some curious facts relating to this subject, will be found in a paper by Professor Daniell, "On certain phenomena resulting from the action of Mercury upon different Metals." (*Royal Instit. Journal*, i. 1.) During the electrolysis of metallic solutions, especially where low powers are employed, beautiful metallic crystals are also occasionally obtained.

Specific Gravity. There is the greatest difference in the *specific gravity* of the different metals, the heaviest and lightest solids being included in the list. Their specific gravity is also in some instances a little increased by hammering, rolling, and some other mechanical processes by which they are permanently compressed.

The principal metals, arranged according to their specific gravities, stand as follows (Temp. 60°, Water = 1):—

Platinum	20.98	Nickel	8.27
Gold	19.258	Iron	7.78
Iridium	18.680	Molybdenum	7.40
Tungsten	17.50	Tin	7.30
Mercury	13.568	Zinc	7.00
Palladium	11.50	Manganese	6.85
Lead	11.35	Antimony	6.70
Silver	10.47	Tellurium	6.10
Bismuth	9.80	Arsenic	5.8
Uranium	9.00	Titanium	5.3
Copper	8.89	Sodium	0.972
Cadmium	8.60	Potassium	0.865
Cobalt	8.53		

Malleability. Among the metals, some are *malleable*, others *brittle*; hence the ancient division into *perfect* and *semi-metals*. Common gold-leaf is not more than $\frac{1}{200000}$ th of an inch in thickness, and five grains are sufficient to cover a surface of more than 270 square inches. This capacity of being extended by the hammer, belongs to the following metals:—

Gold	Tin	Lead	Nickel	Sodium
Silver	Cadmium	Zinc	Palladium	Frozen Mercury.
Copper	Platinum	Iron	Potassium	

Ductility. The malleable metals are also *ductile*; that is, they admit of being drawn out into wires. A grain of gold may be drawn into 500 feet of wire; and by enveloping it in silver, Dr. Wollaston found that it might be so extended, as that 700 feet weighed only one grain; in thickness, therefore, not exceeding $\frac{1}{300000}$ th of an inch. The coating of silver was removed by dilute nitric acid. In the same way he produced platinum wire of similar tenuity. (*Phil. Trans.*, 1813.) The metals are arranged according to ductility as follows:—

Gold	Iron	Tin	Palladium
Silver	Copper	Lead	Cadmium.
Platinum	Zinc	Nickel	

Tenacity. Different metallic wires are possessed of different degrees of *tenacity*, by which is meant the power of supporting a weight without breaking. According to the experiments of Guyton Morveau, the following are the weights sustained by wires 0·787 of a line in diameter (*Ann. de Ch. et Ph.*, LXXI.):—

	lbs. avoir.	dec. parts.		lbs. avoir.	dec. parts.
A wire of iron supports	549	250	A wire of gold supports	150	753
„ copper	302	278	„ zinc	109	540
„ platinum	274	320	„ tin	34	630
„ silver	187	137	„ lead	27	621

Brittleness. The following metals are brittle, and most of them may even be reduced to powder:—

Antimony	Cerium	Columbium	Tellurium	Uranium
Arsenic	Chromium	Manganese	Titanium	Rhodium.
Bismuth	Cobalt	Molybdenum	Tungsten	

Hardness. Few of the metals, when pure, are very *hard*, and many so soft as to yield to the nail. In the following table, some of the metals are arranged in the order of their hardness. (DUMAS.)

Titanium	} Harder than steel.	Chromium	} Scratch glass.
Manganese		Rhodium	
Platinum		Nickel	
Palladium		Cobalt	
Copper		Iron	} Scratched by glass.
Gold	} Scratched by calc-spar.	Antimony	
Silver		Zinc	} Scratched by the nail.
Tellurium		Lead,	
Bismuth		Potassium	
Cadmium		Sodium	} Soft as wax (at 60°).
Tin		Mercury,	
			Liquid.

Elasticity and sonorousness belong to the hardest metals only, and are most evident in certain alloys.

Odour and Taste. There are several of the metals which have a peculiar odour, especially when they are rubbed, or their temperature otherwise slightly elevated; this is more especially the case with copper, iron, and tin. It has been supposed that these metals owe their smell and taste to some foreign matter, and possibly electricity may be concerned; yet many of the most oxidable metals are entirely destitute both of taste and odour.

Fusibility*. The metals are all susceptible of fusion by heat, but the temperatures at which they liquify are extremely various. Mercury is fluid at common temperatures, and requires to be cooled to -39° before it congeals. Potassium melts at about 140° , and sodium at 200° ; tin at 450° ; lead at 600° ; zinc at 700° ; and antimony at 800° . Silver, gold, and copper, require a bright cherry-red heat; iron, nickel, and cobalt, a white heat; manganese and palladium, an intense white heat; molybdenum, uranium, tungsten, and chromium, are only very imperfectly agglutinated at the highest temperatures of our furnaces; and titanium,

* In the examination of the effects of heat upon metallic and mineral substances, the *blowpipe* is a most useful and necessary auxiliary to our other operations; it affords a simple and convenient means of heating to a very high degree, and almost instantaneously, any substance sufficiently small to be enveloped in its flame; and the experienced eye is thus frequently enabled to anticipate, with much precision, the nature of the substance submitted to experiment. There are numerous forms of the blow-pipe, among which, that represented in fig. 269 is perhaps the most convenient. It consists of a brass-tube *a*, with an ivory mouth-piece *b*; the other end of the tube terminates in a circular box, from which issues the small tube *d*, moveable in any direction round the centre *c*, by which any degree of obliquity may conveniently be given to the flame; *e* is a brass jet which fits upon the tube *d*.

The following observations respecting the use of the blow-pipe, and its action upon several substances, are extracted from Mr. CHILDREN'S *Essay on Chemical Analysis*; a work from which the student may derive much valuable information.

A continued stream of air is absolutely essential, to produce which, without fatigue to the lungs, an equable and uninterrupted inspiration must be maintained by inhaling air through the nostrils, whilst that in the mouth is forced through the tube by the compression of the cheeks. A little practice will make this operation easy, but at first considerable lassitude is generally experienced in the buccinator muscles. Upon this subject, see FARADAY'S *Manipulation*, s. iv. After habit has rendered the operation familiar, a current may be kept up for ten or fifteen minutes, without inconvenience. A large wax-candle supplies the best flame, which being urged by the blast, exhibits two distinct figures; the *internal* flame is conical, blue, and well defined, at the apex of which the most violent degree of heat is excited: the *external* is red, vague, and undetermined, and of very inferior temperature to the former.

The substance to be submitted to the action of the blow-pipe, which should not be larger than a small pepper-corn, must be supported either on charcoal, or a slip of platinum or silver foil, or be held in a pair of platinum pincers. In the first case it may be placed in a cavity in the charcoal, and another piece laid over it to prevent its being carried off by the blast. The metallic supports are used when the subject of the experiment is

cerium, osmium, iridium, rhodium, platinum, and columbium, require the intense heat produced by an inflamed current of oxygen and hydrogen, or that of Voltaic electricity. Arsenic volatilizes before it fuses; but in general, at higher temperatures than that required for their fusion, the metals are volatile, and many of them may be distilled in close vessels. Mercury, cadmium, arsenic, potassium, sodium, tellurium, and zinc, are volatile at a red heat. Gold and silver are converted into vapour when exposed to the intense heat of the focus of a burning lens; and several of the other metals boil and evaporate under similar circumstances. It is probable that this would happen to all of them, if raised to sufficiently high temperatures.

intended to be exposed to the action of heat only, and might be altered by contact with the charcoal. If a very intense heat be required, the foil may be laid on charcoal. Salts and volatile substances are to be heated in glass tubes, closed at one end, and enlarged according to circumstances, so as to form small matrasses.

The exterior flame should first be directed on the substance, and when its action is known, then the interior blue flame. Notice should be taken, whether the matter decrepitates, splits, swells up, liquifies, boils, vegetates, changes colour, smokes, is inflamed, becomes obedient to the magnet, &c.: when the action of heat alone has been ascertained, it will be necessary to examine what further change takes place, by fusing it with various fluxes, and also whether it be capable of reduction to the metallic state.

The three most useful fluxes are, the triple phosphate of soda and ammonia, carbonate of soda, and borax. These are to be kept ready pulverized, and when used, a sufficient quantity may be taken up by the moistened point of a knife; the moisture causes the particles to cohere, and prevents their being blown away, when placed on the charcoal. The flux must be melted into a clear bead, and the substance then placed on it, and submitted, first to the action of the exterior, and then to that of the interior, flame. The appearances which ensue must be observed; as, 1st. If the substance be dissolved, and whether with or without effervescence. 2nd. The transparency, and colour of the glass whilst cooling. 3rd. The same circumstances when cold. 4th. The nature of the glass formed by the exterior flame. 5th. Also by the interior flame. 6th. The particular appearances with each of the fluxes.

Carbonate of soda does not form a bead on charcoal, but with a certain degree of heat is absorbed; it must therefore be added in very small quantities, and a gentle heat used at first, which will promote combination without the absorption of the alkali. Some minerals combine readily with very small portions of soda, but difficultly if more be added, and are absolutely infusible with it in great excess; and when the substance has no affinity for this flux, it is absorbed by the charcoal, and no combination ensues. When the mineral contains sulphur or sulphuric acid, the glass acquires a deep-yellow colour, which by the light of a lamp appears red, as if produced by copper. If the glass bead become opaque as it cools, so as to render the colour indistinct, it should be broken, and a part of it mixed with more of the flux, till the colour becomes purer, and distinct. To make the colour more perceptible, the bead may be flattened whilst soft, or drawn-out to a thread.

If it be wished to *oxidate* a metallic substance, combined with either of the fluxes, the glass is first heated intensely, and when fused, gradually withdrawn from the point of the blue flame, and the operation repeated as often as necessary, using a jet of large aperture. The addition of a little nitre also assists the oxidation. For the *reduction* of metallic oxides, the glass bead is to be kept in fusion on charcoal, as long as it remains on the surface and is not absorbed, that the metallic particles may collect into a globule. It is then to be fused with an additional quantity of soda, which will be absorbed by the charcoal, and the spot where the absorption has taken place strongly ignited by a tube with a small aperture. By continuing the ignition, the portion of metal which was not previously reduced will now be

The following table of the fusibility of the metals has been drawn up by Dr. Turner. (*Elements of Chem.*)

		Fahrenheit.	
Fusible below a red heat.	Mercury	-39°	Different Chemists.
	Potassium	136°	Gay Lussac and
	Sodium	190°	Thenard.
	Tin	442°	Crichton.
	Bismuth	497°	
	Lead	612°	
	Tellurium: rather less fusible than lead		Klaproth.
	Arsenic, undetermined.		
	Zinc	773°	Daniell.
	Antimony, little below redness		
	Cadmium	442°	Stromeyer.
	Silver	1873°	Daniell.
Infusible below a red heat.	Copper	1996°	
	Gold	2016°	
	Cobalt; rather less fusible than iron.		
	Iron, cast	2786°	Daniell.
	Iron, malleable	} require the highest heat of a smith's forge.	
	Manganese		
	Nickel, nearly the same as cobalt.		
	Palladium	} Almost infusible, and not to be procured in buttons by the heat of a smith's forge, but fusible before the oxyhydrogen blowpipe.	
	Molybdenum		
	Uranium		
	Tungsten		
	Chromium		
	Titanium		
	Cerium		
	Osmium		
	Iridium		
	Rhodium		
	Platinum		
	Columbium		

ACTION OF OXYGEN.—When the metals are exposed at ordinary temperatures to the action of oxygen, or of common air, which produces analogous, though less powerful effects, they are very differently affected. If the gas be perfectly dry, few of them suffer any change, unless heated in it; they then lose their metallic characters, and form an important series of compounds, the *metallic oxides*. A few of the metals resist the action of heat and air so completely, that they may be kept in fusion in an open crucible for many hours without undergoing change. This is the case with platinum and gold; hence they and a few others were called *noble metals*: by passing a strong electric discharge through them,

brought to the metallic state, and the process may be assisted by placing the bead in a smoky flame, so as to cover it with a soot that is not easily blown off.

The beads which contain metals frequently have a metallic splendour, which is most easily produced by a gentle, fluttering, smoky flame, when the more intense heat has ceased. With a moderate heat the metallic surface remains; and by a little practice it may generally be known whether the substance under examination contains a metal or not.

But the glass of borax alone sometimes assumes externally a metallic appearance. When the charcoal is cold, that part impregnated with the fused mass should be taken out with a knife, and ground with distilled water in an agate mortar. The soda will be dissolved; the charcoal will float, and may be poured off; and the metallic particles will remain in the water, and may be examined. In this manner most of the metals may be reduced.

when drawn into very fine wire, they are reduced to the state of impalpable powder, which is sometimes regarded as an oxide; but the appearance ensues in hydrogen as well as in common air, and the oxides of those metals are reducible by heat alone: the appearance, therefore, is probably referable to minute mechanical division only. Other metals readily absorb oxygen when exposed to a temperature approaching a red heat; as iron, mercury, nickel, &c.; others absorb it when in fusion, as lead, tin, antimony, &c.; others at lower, or even at common temperatures, as arsenic, manganese, sodium, potassium, &c. The mutual action, however, of metals and oxygen is apparently much interfered with by their aggregation, for some of them, which under ordinary circumstances are only slowly oxidized by exposure to air and heat, are rapidly acted on when in very fine mechanical division, even at common temperatures; and this would probably be found more generally the case, had we the means of reducing them to extremely fine powder.

That the metals have different attractive powers in regard to oxygen is shown by the circumstance of one metal being oxidized at the expense of another: thus the oxide of mercury, heated with metallic iron, produces metallic mercury and oxide of iron; potassium, heated with oxide of manganese, becomes oxidized, and metallic manganese is obtained. Upon the same principle, solutions of metallic oxides in the acids may often be reduced to the metallic state by the immersion of other metals. Mercury thus decomposes nitrate of silver; copper decomposes nitrate of mercury; and iron decomposes nitrate of copper. In these cases of metallic precipitation, electricity becomes active the moment that the deposition commences; the precipitating or reducing metal being positive, and that which is precipitated, or reduced, negative. Very beautiful crystalline deposits may thus often be obtained, as where silver is precipitated by mercury, and lead by zinc. Metals which are in this way difficultly thrown down from their solutions in acids, are sometimes easily obtained from their solutions in alkalis, as for instance tungsten and tin.

Many of the metallic oxides are reduced, when in solution, by the protosalts of iron and tin, which by abstracting oxygen pass into the state of persalts, and throw down the reduced metal in a pulverulent form. The protosalts of iron are in these cases preferable to those of tin, inasmuch as the resulting peroxide of iron is retained in solution, and the precipitated metal is pure; but the peroxide of tin often falls along with the reduced metal, in consequence of its difficult solubility in most of the acids.

Some of the oxides are decomposed by mere exposure to heat, as those of platinum, gold, silver, and mercury: others require the joint action of heat, and some substance having a high attraction for oxygen, such as charcoal. Thus when oxide of lead is heated with charcoal, carbonic acid gas is evolved, and metallic lead obtained. This important process is termed *reduction*, and is performed in various ways, as will appear by reference to the history of individual metals. The reduction of an oxide is also frequently effected by passing a current of dry hydrogen over it in a heated tube; in this case the oxygen is carried off in the form of water. Sometimes the reduction of an oxide is effected by the aid of another

metal possessed of a very superior attraction for oxygen, as in the cases cited in the preceding paragraph; and in some cases complicated attractions are directed to the process of reduction, as in the production of potassium by the action of red-hot iron upon hydrate of potassa.

Electricity is an all-powerful agent in metallic reduction, and capable, under certain circumstances, of overcoming the most energetic attractions. This important subject has been discussed and illustrated in a former chapter (p. 307).

Some of the metallic combinations, especially those of gold, are reducible by the agency of *light* (p. 200); the salts of silver are also discoloured or partially reduced by the same agency.

The oxidizement of a metal is an essential preliminary to the formation of its oxy-salts, or, in other words, to its combinations with oxy-acids; and in this respect common chemical nomenclature is inaccurate. Thus we speak of sulphate of *copper*, nitrate of *zinc*, &c., meaning sulphate of *oxide* of copper, nitrate of *oxide* of zinc, &c. This ambiguity is prevented with respect to the alkalis and alkaline earths, the oxides of their bases being characterized by a distinct termination: thus phosphate of *soda* means phosphate of *oxide of sodium*, &c.; a circumstance which induced Sir H. Davy to propose an analogous termination for all the oxides, appropriately applied to their common Latin names: *Cupra*, oxide of copper; *Argentæ*, oxide of silver, &c.; but this proposal, which he extended to other compounds, was never adopted.

Each metal has a certain definite quantity of oxygen with which it combines; and where the same metal unites in more than one proportion with oxygen, in the second, third, and other compounds, it is a multiple of that in the first, consistent with the law of definite proportionals. Thus, 100 parts of mercury combine with 4 of oxygen to produce the black oxide, and with 8 to produce the red oxide. Copper also forms two oxides; in the one 12.5 of oxygen are united to 100 of metal, and in the other 25. Where two oxides only are thus formed, that with the minimum of oxygen is termed the *protoxide*, and that with the maximum of oxygen the *peroxide*; where there are three or four distinct steps of oxidizement, the terms *deutoxide* or *binoxide*, and *tritoxide* or *teroxide*, may be applied to the second and third stages; and where the proportion of oxygen, in three oxides, is in the relation of 1, $1\frac{1}{2}$, and 2, the second is termed a *sesquioxide*.

M. F. de Montizon has attempted to show (*Ann. de Ch. et Ph.*, vii. 7) that a relation subsists between the quantity of oxygen with which the metals combine, and their specific gravities; the oxygen being a multiple or submultiple of the density; and he has given a table comparing the results deduced from such a theory, with those obtained by analysis.

In reference to an hypothesis originally propounded by Davy (*Elem. of Chem.*), respecting the possible existence of hydrogen in the metals, and of water in their oxides, Gay Lussac has observed that the lightest metals are those which absorb most oxygen in becoming oxides; and that the heavier or denser metals, on the contrary, absorb less oxygen; in other words, the denser metals are those which have the higher equivalents, the lighter metals being represented by lower numbers: this law, though not rigorously exact, is sufficiently so to deserve attention, and if, selecting

certain metals they be divided into two groups, it will be found that where the specific gravity varies from 10 to 20, the atomic weight is about or above 100, but that where the specific gravity is between 8 and 1, or below 1, the atomic weight is about 30.

I.			II.		
Metal.	Sp. Gr.	Atomic Weight.	Metal.	Sp. Gr.	Atomic Weight.
Platinum	20.98	99	Cobalt	8.53	30
Gold	19.20	200	Copper	8.89	32
Iridium	18.60	96	Nickel	8.27	28
Tungsten	17.50	100	Iron	7.78	28
Mercury	13.56	200	Zinc	7.00	32
Lead	11.35	104	Manganese	6.85	28
Silver	10.47	108	Sodium	0.97	24

Among the combinations of metals with oxygen, some are insoluble in water, or nearly so, and have neither taste nor smell; others are soluble and sour, constituting the *metallic acids*; others are soluble and alkaline, forming the *fixed alkalis* and *alkaline earths*. They are of all colours, and frequently the same metal united to different proportions of oxygen produces compounds differing in colour: thus we have the *black* and *red* oxide of mercury, the *green* and the *black* oxide of manganese, &c.

The different oxides of the same metal frequently form distinct salts with the acids, and the quantity of acid required to neutralize the oxide bears a direct proportion to the oxygen which it contains. Thus, 208 parts of protoxide of mercury, containing 8 of oxygen, combine with 40 of sulphuric acid to form the *protosulphate of mercury*; and 216 parts of the peroxide of mercury, containing 16 of oxygen, require 80 of sulphuric acid to constitute the *persulphate of mercury*. This law was first developed by Gay Lussac (*Mémoires d'Arcueil*, ii. 159). It sometimes happens that the same oxide unites with an acid in two proportions, forming two distinct salts, in which case the acid in the second is a multiple of that in the first. Thus, 48 parts of potassa unite to 22 and to 44 of carbonic acid, forming a *carbonate* and a *bicarbonate* of potassa. We thus have an *oxalate*, a *binoxalate*, and a *quadroxalate*, of potassa, &c.

The metallic oxides occasionally combine with each other, forming definite compounds; instances of such combinations are common in the mineral kingdom: in this case one of the oxides appears to perform the part of an acid, and the other that of base. Many of the compounds of silica furnish illustrative instances. The salts of the proper metallic acids are also analogous compounds.

ACTION OF CHLORINE.—All the metals appear susceptible of combining with chlorine, and of producing a class of compounds which may be termed *metallic chlorides*. There are a few of the metals which resist the action of chlorine at common temperatures, but when heated they all combine with it; some slowly; others rapidly, and with intense ignition. Copper-leaf, powdered antimony, arsenic, &c., burn when thrown into the gas: mercury and iron inflame when gently heated in it; silver, gold, and platinum, quietly absorb it. In these cases, minute mechanical division remarkably accelerates the action. The attraction of chlorine for metals is greater than that of oxygen; consequently when a metallic oxide is heated in chlorine, oxygen is evolved, and a chloride formed.

The insoluble chlorides are also formed by adding solution of chlorine, or of the soluble chlorides, or of hydrochloric acid, to the soluble metallic salts. Thus chloride of silver, which is insoluble, is thrown down from the soluble nitrate of silver by solution of chlorine, of hydrochloric acid, and of common salt: hence, too, all the soluble chlorides are recognised, by yielding a white precipitate with solution of nitrate of silver, which is soluble in ammonia, and which, when pure, rapidly blackens by exposure to the sun's rays.

The physical and chemical properties of the chlorides are extremely various. They are nearly of all colours. They are generally unchanged by heat; but some undergo decomposition. Some are soluble, others insoluble, in water. Some permanent; others deliquescent. Several of them decompose water, and form hydrochloric acid, and an oxide. The question respecting the action of water upon the chlorides has given rise to several hypotheses founded on their mutual decomposition, some of which will be adverted to under specific heads. (See DUMAS, in reference to this question. *Ann. de Ch. et Ph.*, xlv. p. 263.) Many of them absorb ammonia, and some in considerable quantity. They are fusible, and most of them crystallizable. Some are extremely volatile at common temperatures, and others fixed in high heats. A few exist, at all ordinary temperatures, in the liquid state. They are generally decomposed by a red heat by hydrogen, which produces hydrochloric acid, and reduces the metal. Anhydrous sulphuric acid appears not to act upon them; but the common hydrated acid decomposes them, with few exceptions, evolving hydrochloric acid: the theory of these changes is elsewhere explained. (See *Chloride of Sodium*.) Some of the metals rapidly decompose certain chlorides in consequence of their superior attraction: thus chloride of silver is decomposed by zinc, &c.

The same metal often forms more than one compound with chlorine, and these compounds are designated as the oxides. Thus we have the *protochloride* and *bichloride* or *perchloride* of mercury, *sesquichloride* of antimony, &c.

Many of the metals decompose hydrochloric acid, in which case hydrogen is evolved, and a metallic chloride produced; and when metallic oxides are heated in hydrochloric acid, they generally give rise to the formation of a chloride and water. (See page 399, &c.)

There are a few metallic oxides which, at low temperatures, absorb and retain chlorine, but they hold it by very feeble attraction. The chlorides of potassa and of lime will be described under those bodies. It has also been combined with the oxides of iron, zinc, and copper. (GROUVELLE, *Ann. de Ch. et Ph.*, xvii.) These compounds are decomposed by heat and by the acids.

ACTION OF CHLORIC ACID.—The compounds of the metallic oxides with chloric acid, or *chlorates*, are decomposed by heat with the copious evolution of oxygen, and a chloride generally remains: they deflagrate when triturated with charcoal or other combustibles. In the neutral chlorates the proportion of oxygen in the base to that in the acid is as 1 to 5: some of these salts have been long known, others only recently investigated. The *oxychlorates*, or *perchlorates*, have been scarcely

examined. Like the chlorates, they yield oxygen when heated: and the proportion of oxygen in the base to that in the acid is as 1 : 7.

ACTION OF IODINE.—Iodine, aided by heat, acts upon many of the metals, and produces *metallic iodides*. Some of these are soluble in water without decomposition; others decompose water; others are insoluble. The insoluble iodides may generally be formed by adding a solution of iodine or of hydriodic acid, or of an iodide, to the soluble metallic salts. Iodine often combines in more than one proportion with metals, forming *protiodides*, *sesquiodides*, *biniodides*, &c. The iodides are decomposed by chlorine and bromine, and some by oxygen; but in other instances iodine expels oxygen from its combinations with the metals. Iodides are also decomposed by nitric and by sulphuric acid; and in all these cases the free iodine is easily recognised by starch. According to Gay Lussac, when the vapour of iodine is passed over hot lime, baryta, and strontia, it does not expel their oxygen, but unites with them as oxides. These compounds are not very permanent, and are decomposed at a temperature a little exceeding that required to form them.

ACTION OF IODIC ACID.—The compounds of this acid with the metallic oxides have been but little examined: they are decomposed and converted into iodides by heat, sometimes with the evolution of oxygen only; at others, iodine is also given off.

ACTION OF BROMINE.—Bromine combines with the metals and produces *bromides*, analogous in their general habitudes to the chlorides and iodides; they are formed either by the direct action of bromine on the metal, or by that of hydrobromic acid upon the metallic oxide; or, when insoluble, they are precipitated by the addition of the soluble bromides to metallic solutions. Bromine also unites to some of the metallic oxides, and produces bleaching compounds. Chlorine disengages bromine from its binary metallic compounds, and bromine expels iodine from the iodides; so that the attraction of bromine for the metals is intermediate between chlorine and iodine. (See a Memoir on the Bromates by M. BERTHEMOT, *Ann. de Ch. et Ph.*, xlv. 382.)

The *Bromates* are little known. When heated to redness they become *bromides*, by the loss of oxygen.

ACTION OF FLUORINE.—As fluorine has not been obtained in a separate state, its immediate action upon the metals is not known; but it would probably be energetic. Such of the *fluorides* as are insoluble may be obtained by the medium of a solution of fluoride of potassium, or by precipitation by hydrofluoric acid: the soluble fluorides are formed by digesting the oxides in the hydrofluoric acid. The fluorides are not decomposed by oxygen, chlorine, iodine, or bromine; but they are immediately recognised by the evolution of hydrofluoric acid, when moistened and heated with sulphuric acid, and by their action upon glass under such circumstances.

ACTION OF HYDROGEN.—Hydrogen forms permanent compounds with two of the metals only, namely, arsenic and tellurium. It appears to combine with each in two proportions, forming two solid compounds, the *hydrurets* or *hydrogurets* of arsenic and tellurium; and two gaseous

compounds, *arseniuretted* and *telluretted hydrogen*. At high temperatures it dissolves potassium, forming *potassiuretted hydrogen gas*. Hydrogen also appears to combine with zinc and antimony, at least it frequently retains a little of those metals in its gaseous state.

There are many of the metallic oxides and chlorides, which are decomposed by hydrogen: the oxides are reduced with the formation of water, and the chlorides with the production of hydrochloric acid.

ACTION OF WATER.—Those metals which are speedily acted upon by common air and oxygen, are also generally capable of decomposing water; some of them rapidly, others slowly. There are some metals which are not acted upon by air deprived of moisture, nor by water deprived of air; but moist air, or water containing air, effects their oxidizement: this appears to be the case with iron, (Dr. MARSHALL HALL, *Quarterly Journal*, vii. 55,) and also with lead. Water combines with many of the metallic oxides, and produces *hydrated oxides*, or *metallic hydrates*. In these the relative proportion of water is definite. Some are easily decomposed by very moderate heat, as hydrate of copper; others retain water even when heated to redness, as hydrate of potassa; others are decomposed at a red heat, as hydrate of lime.

ACTION OF NITRIC ACID.—The greater number of metals are capable of decomposing nitric acid by the abstraction of a part of its oxygen, and thus of resolving it into some of the other nitric compounds; nitric acid is a very generally acting solvent, therefore, of these bodies. It dissolves nearly all the metallic oxides, and produces a numerous class of *nitrates*, which, if prepared with heat and with excess of acid, generally contain the metal at its maximum of oxidizement. The nitrates are all decomposed by a red-heat; they give off oxygen and nitrogen, either separate or combined, and the metallic oxide remains. They are also decomposed when heated with sulphur, phosphorus, or charcoal; and sulphurous, phosphoric, and carbonic acids are formed: the phosphoric, being a fixed acid, remains united to the metallic oxide; while the sulphurous and carbonic acids are usually expelled. The nitrates are decomposed by sulphuric acid, nitric acid is evolved, and *sulphates* are formed. In the neutral nitrates the proportion of oxygen in the acid is to that in the base as 5 to 1. Thus in the nitrate of potassa, 48 parts of potassa, containing 8 of oxygen, are combined with 54 of nitric acid, containing 40 (8×5) of oxygen; and in the nitrate of oxide of copper, 40 parts of oxide of copper, containing 8 of oxygen, are combined with 54 of nitric acid, containing 40 of oxygen.

ACTION OF AMMONIA.—At high temperatures some of the metals are capable of decomposing ammonia. Liquid ammonia dissolves several of the metallic oxides, and with some of them forms crystallizable compounds. It dissolves the oxides of silver, copper, zinc, arsenic, antimony, and tellurium; the protoxides of iron, cobalt, and nickel; and the peroxides of tin, mercury, gold, and platinum. These compounds are all decomposed by heat. The compounds of ammonia with the oxides of gold, silver, and platinum, detonate when heated, and the oxide and the ammonia are both decomposed. The combinations of ammonia with several anhydrous salts have been examined by H. Rose (*Ann. de Ch. et Ph.*, lxii. 308).

ACTION OF SULPHUR.—All the metals appear capable of combining with sulphur and forming *sulphurets*. These are obtained, 1st, By heating the metal in a close vessel, with sulphur; and it not unfrequently happens that, during the combination, the metal becomes intensely ignited, burning as it were in the vapour of the sulphur, and furnishing a striking instance of combustion without the presence of oxygen; this is the case with potassium and sodium, and with the filings or shavings of copper, lead, and iron. 2ndly, By heating a mixture of sulphur and a metallic oxide, in which case sulphurous acid escapes, and the metallic sulphuret remains behind. 3rdly, By decomposing the *sulphates*, either by subjecting them to the action of a current of hydrogen gas in a heated tube, or by heating a mixture of the sulphate with charcoal. 4thly, By the action of sulphuretted hydrogen. 5thly, By fusing the metallic oxide with a mixture of carbonate of potassa and sulphur, in which case an alkaline sulphuret is first formed, and sustains a red heat, but at that temperature a proportion of its sulphur is imparted to the reduced metal of the oxide. The sulphurets are in general brittle; some have a metallic lustre, and are opaque; others are without lustre, and more or less transparent. Some are fusible, and some volatile. Some are soluble, but the greater number insoluble in water. Where the same metal forms two sulphurets, the sulphur in those containing the largest proportion is a simple multiple of the sulphur in those containing the smallest proportion; hence we have metallic *sulphurets*, *bisulphurets*, and *sesquisulphurets*; and, generally speaking, the sulphurets correspond in number and atomic composition with the oxides. When the metallic sulphurets are heated in close vessels, some undergo no change, as those of sodium and potassium; others sublime unaltered, as sulphuret of mercury and sulphuret of arsenic; others lose a portion of their sulphur, and, if air be admitted, sulphurous acid escapes, and the metal passes into the state of oxide, as sulphuret of lead and sulphuret of copper; and it is thus that these sulphurets are oxidized by the process called *roasting*, previous to their reduction, upon the large scale; others again are entirely decomposed, the metal being completely reduced; this happens on heating sulphuret of platinum or of gold. Definite compounds of sulphur with some of the metallic oxides, have been obtained by Arfwedson (*Ann. de Ch. et Ph.*, vi. 204).

There are certain double sulphurets, which Berzelius has designated *sulphur salts*; in these cases he terms the electronegative sulphurets, *sulphur acids*; and the electropositive sulphurets, *sulphur bases*; among the *sulphur acids*, he enumerates the sulphurets of arsenic, antimony, gold, molybdenum, tellurium, tin, and tungsten; he also calls sulphuretted hydrogen, sulphocyanogen, sulphuret of selenium, and sulphuret of carbon, *sulphur acids*. The principal *sulphur bases* are the proto-sulphurets of the metals of the alkalis and alkaline earths, and the hydro-sulphuret of ammonia (sulphuret of ammonium).

HYPOSULPHUROUS ACID combines with the metallic oxides, and produces a class of salts termed *hyposulphites*. Several of these have been examined by Herschel. (*Edin. Phil. Journal*, i.) In some of their characters they resemble the sulphites: they are easily soluble; of a bitter or

sweet taste ; and decomposed by a heat below redness, and by almost all other acids. Their solutions readily dissolve chloride of silver.

SULPHUROUS ACID combines with many of the metallic oxides, producing *sulphites*; in some instances oxygen is transferred from the oxide to the acid, and sulphates result.

The *sulphites* are soluble in water, and have a sulphurous taste and smell. Exposed to moist air, they absorb oxygen, and pass into the state of sulphates. They are decomposed by sulphuric acid, which expels sulphurous acid, and the salts are converted into sulphates. When perfectly pure they are not affected by solution of baryta.

HYPOSULPHURIC ACID forms with the metallic oxides a class of *hyposulphates*. They do not afford precipitates with solution of baryta. When heated they evolve sulphurous acid, and are converted into neutral sulphates: when their solutions are boiled with sulphuric acid, sulphurous acid is evolved, but no sulphur is precipitated.

SULPHURIC ACID, in its concentrated state, and unaided by heat, is acted upon by a few of the metals only; when diluted, some of them are oxidized at the expense of the water, hydrogen is evolved, and the metallic oxide combines with the acid, producing a *sulphate*. In these cases the hydrogen evolved is the indicator of the quantity of oxygen transferred to the metal; every volume of hydrogen is the equivalent of half a volume of oxygen, and accordingly the production of 100 cubic inches of hydrogen indicates the transfer of 50 of oxygen, or, by weight, of about 17.3 grains. As different metals unite to different weights of oxygen, they will obviously evolve different quantities of hydrogen. Thus, if one metal, to become soluble in sulphuric acid, require to be united with 10, and another with 20 per cent. of oxygen, the latter will evolve twice the volume of hydrogen, compared with the former. As the evolution of hydrogen, during the solution of a metal in dilute sulphuric acid, is referable to its oxidizement, no hydrogen will be evolved by the action of the acid upon an oxide, but it will be merely dissolved.

The sulphates are an important class of salts. The greater number of them are soluble in water, and the solutions yield a precipitate with the soluble salts of baryta which is insoluble in acids and alkalis. The insoluble sulphates may be recognised by igniting them in fine powder with thrice their weight of carbonate of soda, by which a soluble sulphate of soda is formed: it may be separated by water and filtration, crystallized, and tested by nitrate of baryta. The sulphates of potassa, soda, lithia, lime, baryta, and strontia, resist a white heat without decomposition: the other sulphates evolve, when intensely heated, sulphuric acid, sulphurous acid, and oxygen. Many of them are decomposed at high temperatures by the action of hydrogen, which carries off the oxygen of the acid, and of the base, and leaves a metallic sulphuret. In some cases the sulphur also combines with the hydrogen, and the sulphate thus affords a reduced metal. They are all decomposed at a red heat by charcoal, and most of them are thus converted into sulphurets; carbonic acid, and carbonic oxide, being at the same time evolved. In the neutral sulphates the proportion of oxygen in the acid is to that in the base as 3 to 1. Thus sulphate of soda is composed of 32 soda, containing 8 of oxygen, combined with 40 of sulphuric acid, containing 24 (8×3) of oxygen; and in the sulphate of copper, 40

parts of oxide of copper, containing 8 of oxygen, are combined with 40 of sulphuric acid, containing 24 (8×3) of oxygen. Many of the anhydrous sulphates absorb ammoniacal gas, forming definite compounds which are decomposed by heat. (H. ROSE, *Ann. de Ch. et Ph.*, Lxii. 309.)

ACTION OF SULPHURETTED HYDROGEN.—When sulphuretted hydrogen combines with metallic sulphurets, it forms one class of the *sulphur-salts*. It seems doubtful whether any of the metals combine with sulphuretted hydrogen. Its combinations with their oxides have been termed *hydrosulphates* or *hydrosulphuretted oxides*, but it generally happens that in the mutual action of the sulphuretted hydrogen and the oxide, both are decomposed, the hydrogen combining with the oxygen of the oxide to form water, and the sulphur uniting to the metal to form a metallic sulphuret. In a few cases the metallic oxide is reduced. Occasionally a compound of a metallic sulphuret and a salt of the oxide is thrown down; thus when sulphuretted hydrogen is passed through a solution of per-nitrate of mercury, the latter being in excess, the precipitate is a definite compound of pernitrate and sulphuret of mercury. (H. ROSE, *Ann. de Ch. et Ph.*, Lxvi. 366.) The following table shows the effect of sulphuretted hydrogen and of sulphuretted hydrosulphuret of ammonia upon solutions of several of the metals, as far as *colour* of the precipitate is concerned, these precipitates being often resorted to as qualitative tests.

METAL.	SOLUTION.	SULPHURETTED HYDROGEN.	HYDROSULPHURET OF AMMONIA.
MANGANESE .	Neutral protochloride	No precipitate	Copious ochre-yellow
IRON . . .	Neutral protosulphate	Blackish and small in quantity	Black and abundant
Ditto . . .	Perchloride	Abundant black	Black
ZINC . . .	Chloride	A little opalescent and then milky	Straw-colour and copious
TIN	Acid protochloride	Brown	Deep orange
Ditto . . .	Acid perchloride	At first 0, then yellow and copious	Apple-green
CADMIUM . .	Chloride	Yellow	Yellow
COPPER . . .	Protochloride	Deep brown	Brown
Ditto . . .	Nitrate	Black	Brown and black
LEAD	Chloride and nitrate	Ditto	Ditto
ANTIMONY . .	Tartrate of antimony and potassa	Deep orange-red	Bright orange
BISMUTH . .	Tartrate of bismuth and potassa	Deep brown	Deep brown
COBALT . . .	Chloride	0 but blackish	Copious black
URANIUM . .	Sulphate	Brown	Blackish brown
TITANIUM . .	Acid chloride	0	Black

ACTION OF SELENIUM.—Selenium acts upon the metals with nearly the same phenomena as sulphur, and in their general characters the *seleniurets* and sulphurets are analogous: when heated in the open fire the selenium burns slowly off with an azure flame, and the odour of radish. The atomic composition of the seleniurets follows that of the sulphurets, and they are best obtained by precipitating the metallic solutions with seleniuretted hydrogen, and then, if biseleniurets are required, the precipitate may be fused with selenium, and the excess driven off by distillation. The *selenites* and *seleniates* are decomposed by sulphurous acid, which throws down the selenium of a red colour in the cold, and nearly black at a boiling-heat. Distilled with hydrochlorate of ammonia, selenium passes over. In the selenites the oxygen in the acid is to that in the base as 2 to 1, and in the seleniates as 3 to 1; these salts, therefore, are isomorphous with the sulphites and sulphates.

ACTION OF PHOSPHORUS.—Phosphorus combines with the greater number of the metals, forming a series of *metallic phosphurets*. There are three methods of forming them; either by heating a mixture of phosphorus and the metal, or projecting phosphorus upon the metal previously heated to redness; or by heating a mixture of the metal or its oxide, with phosphoric acid and charcoal; or by passing phosphuretted hydrogen over the heated metallic oxide. A very few only of the phosphurets can be obtained in the humid way, for when phosphuretted hydrogen is passed through metallic solutions the metal is either reduced, as in the case of the salts of gold and silver; or peculiar compounds ensue, composed of the metallic salt and the phosphuret, as when the salts of peroxide of mercury are decomposed by phosphuretted hydrogen; or no change takes place, as with the greater number of metallic salts. The only case of the production of a pure phosphuret by this process appears to be that of phosphuret of copper, which is thrown down whenever phosphuretted hydrogen is passed through solutions of the salts of that metal. (H. ROSE, *POGGEND. Ann.*, xxiv. 320; and *Ann. de Ch. et Ph.*, lxvi. 366.) The phosphurets have a metallic lustre; if they contain a difficultly-fusible metal, they are more fusible than the metal they contain; if an easily-fusible metal, less so. They are mostly crystallizable, and totally or partly decomposable at a high temperature. The greater number of the phosphurets have only been examined by Pelletier (*Ann. de Ch.*, tom. i. and xiii., and *Mémoires et Observations de Chimie*). The existence of compounds of metallic oxides with phosphorus appears doubtful.

When phosphorus is introduced into the solutions of those metals which have but a feeble attraction for oxygen, it reduces them to the metallic state. Thus gold, silver, and platinum are thrown down by immersing a stick of phosphorus into their respective solutions.

The *Hypophosphites* and the *Phosphites* have been imperfectly examined. When heated they evolve phosphorus or phosphuretted hydrogen, and are converted into phosphates: their solutions smell of phosphorus, and reduce the salts of gold, silver, and mercury.

ACTION OF PHOSPHORIC ACID.—The *metallic phosphates* may be formed either by dissolving the oxides in phosphoric acid, or by adding a solution of phosphoric acid, or of an alkaline phosphate, to solutions of

those metals which form insoluble or difficultly-soluble phosphates. The greater number of the phosphates are decomposed and converted into phosphurets, by ignition with charcoal: and those containing volatile oxides are volatilized at high temperatures. The phosphates of ammonia, potassa, and soda, are soluble; but the greater number of these salts are difficultly soluble, and some insoluble in water: they are dissolved by phosphoric, nitric, and hydrochloric acids, and precipitated, generally without change, by ammonia. Those which are insoluble are mostly decomposed by boiling with carbonate of potassa. Several of the phosphates occur in the native state, constituting some beautiful but generally rare minerals.

In the neutral phosphates the quantity of oxygen in the acid is to that in the base as 2·5 to 1. Thus, phosphate of soda consists of 32 soda containing 8 oxygen, and 36 phosphoric acid containing 20 ($8 \times 2\cdot5$) of oxygen. But the phosphoric acid unites to bases in several other proportions, giving rise to a variety of subsalts and supersalts, of which the most important will be noticed in the sequel.

ACTION OF CARBON.—Carbon unites to very few of the metals; and of the metallic *carburets*, one only is of importance, namely, carburet of iron, which constitutes the varieties of cast-iron, and steel.

When some of the metallic cyanurets, and certain of the salts of metallic oxides and organic acids are decomposed by heat, the residuary products appear to be, in some cases, true carburets; these, however, have been but imperfectly examined.

CARBONIC ACID unites with the greater number of the metallic oxides, and forms *carbonates*, of which the distinctive characters have already been noticed; most of them are of difficult solubility, and may be formed by adding an alkaline carbonate to the metallic solution. Of the carbonates some are entirely, and others only partially, decomposed at a red heat. Carbonate of magnesia, for instance, loses the whole of its carbonic acid at a red heat; carbonate of potassa retains it; and bicarbonate of potassa loses one-half, and passes into the state of carbonate. The carbonates are decomposed by nearly all the other acids, and are then distinguished by the effervescence that ensues on the escape of carbonic acid gas.

In the neutral carbonates the proportion of oxygen in the base is to that in the acid as 1 to 2. Carbonate of potassa, for instance, consists of 48 of potassa containing 8 of oxygen, and 22 of carbonic acid, containing 16 (8×2) of oxygen.

The carbonates are not uncommon natural products.

CYANOGEN combines with many of the metals, and forms compounds, which we call *cyanurets*, or *cyanides*. The compounds of the *cyanic acid*, or the *cyanates*, are so decomposed, either by the action of water, or the acids, that the cyanic acid is resolved into carbonic acid and ammonia, with no trace of hydrocyanic acid. The *fulminates* explode when heated, and evolve hydrocyanic acid by the action of the oxyacids. The *Hydrocyanates* have been but imperfectly examined; they appear peculiarly susceptible of decomposition.

Sulphocyanurets and *Sulphocyanates* produce a characteristic red colour when added to a solution of persulphate of iron.

THE ACTION OF BORON upon the metals has not been fully investigated.

THE BORATES of the alkalis are soluble: with other bases the boracic acid mostly forms difficultly-soluble or insoluble compounds, which are easily formed by adding solution of boracic acid, or a soluble borate to the metallic solution. The borates are generally decomposed in the humid way, by sulphuric, nitric, and hydrochloric acids; but, at a red heat, the boracic acid expels the more volatile acids from their basic compounds. The presence of this acid may in many instances be detected by digesting its compounds in sulphuric acid, evaporating to dryness, and boiling the residue in alcohol, which will then be found to burn with a characteristic green flame. (See *Boracic Acid*.)

ACTION OF THE METALS UPON EACH OTHER.—The metals may, for the most part, be combined with each other, forming a very important class of compounds, the *metallic alloys*. In the act of combination they generally evolve heat; thus, when platinum and tin-foil are fused together, there is vivid ignition; so, also, when melted zinc and copper are suddenly mixed in the proportions to form brass, the increase of heat is such as to vaporize part of the metal. Various processes are adopted in the formation of alloys, depending upon the nature of the metals. Many are prepared by simply fusing the two metals in a covered crucible; but if there be a considerable difference in the specific gravity of the metals, the heavier will often subside, and the lower part of the bar or ingot will differ in composition from the upper; this may be to a great extent prevented by agitating the alloy till it solidifies. Mr. Hatchett found that when an alloy of gold and copper was cast into bars, the moulds being placed perpendicularly, the upper part of the bar contained more copper than the lower (*Phil. Trans.*, 1803); and although copper and silver appear readily to combine, it is extremely difficult to form a bar of their alloy, of perfectly uniform composition throughout.

Where one of the metals is very volatile, it should generally be added to the other after its fusion; and if both metals be volatile, they may be sometimes united by distilling them together.

It has been a question whether alloys are to be considered as compounds, or as mere mixtures; but, in many cases, their properties leave little doubt of their being real compounds, and in some cases they are found to unite in definite proportions only; and it is not improbable that all the alloys contain definite compounds of the metals. It is observed by Berzelius, that the acidifiable metals have the greatest tendency to combine with those which produce salifiable bases, and that arsenic, antimony, and tellurium, form definite compounds analogous to sulphurets and phosphurets, which are not uncommon as ores. Among the artificial, as well as the natural alloys, there are many which are crystallizable, and the true compound may sometimes be separated from the mere mixture of the metal by its tendency to crystallize.

The principal characters of the alloys are the following:—i. We observe a change in the ductility, malleability, hardness, and colour. Malleability and ductility are usually impaired, and often in a remarkable degree: thus gold and lead, and gold and tin, form a brittle alloy. The alloy of copper and gold is harder than either of its component parts; and a minute quantity of arsenic added to copper renders it white.—ii. The specific gravity of an alloy is rarely the mean of its component parts, in some cases an increase, in others a diminution of density having taken place, as shown in the following table from Thenard (*Traité de Chimie*, vol. i., p. 394):—

Alloys possessed of greater specific gravity than the mean of their components.

Gold and Zinc
" Tin
" Bismuth
" Antimony
" Cobalt
Silver and Zinc
" Lead
" Tin
" Bismuth
" Antimony
Copper and Zinc
" Tin
" Palladium

Tin and Lead
" Palladium
" Antimony
Nickel and Arsenic
Zinc and Antimony.

iii. The fusibility of an alloy is generally greater than that of its components. Thus platinum, which is infusible in our common furnaces, forms, when combined with arsenic, a very fusible alloy; and an alloy of certain proportions of lead, tin, and bismuth, is fusible at 212° , a temperature many degrees below the melting-point of its most fusible constituent.

iv. Alloys are generally more oxidizable than their constituents, taken singly; a property which is, perhaps, partly referable to the formation of an electrical combination. Where an alloy consists of two metals, the one easily and the other difficultly oxidizable, it may be decomposed by exposing it to the action of heat and air, the former metal being converted into an oxide: its last proportions, however, are often not easily separated, being protected by combination with the least oxidizable metal. An alloy of three parts of lead and one of tin is infinitely more oxidizable than either of its components, and easily burns at a dull-red heat.

v. The action of acids on alloys may generally be anticipated by a knowledge of their effects upon the constituent metals; but if a soluble metal be alloyed with an insoluble one, the former is often protected by the latter from the action of an acid. Thus, silver alloyed with a large quantity of gold, resists the action of nitric acid in consequence of the

insolubility of the latter metal in that acid; and, in order to render it soluble, it is requisite that it should be made to form about a fourth part of the alloy, in which case the nitric acid extracts it, and leaves the gold in an insoluble film or powder.

In other cases a metal insoluble, or nearly so, in certain acids, *per se*, is taken up in considerable quantity when alloyed; thus, platinum is insoluble in nitric acid, but its alloy with silver is to a certain extent soluble; and when a triple alloy of gold and silver with a little platinum is rolled out and digested in nitric acid, both the silver and the platinum are taken up. Rhodium is insoluble in acids, but, when alloyed with copper or lead, the nitrohydrochloric acid dissolves it.

Various classifications of the metals have been adopted by chemical authors*, some dependent upon their *physical*, others upon their *chemical* properties. The former can scarcely be considered as adapted to chemical inquiry, and the latter involve numerous difficulties in consequence of the gradual transition of metals of one class into those of another. I shall consider the metals in the order in which they are set down in the following table, and which is nearly that of their respective attractions for oxygen, with the exception of the last division, which includes substances in part imperfectly examined, and from which, as already remarked, silicium ought probably to be excluded.

I.	II.	III.	IV.	V.	VI.
1 Potassium	8 Manganese	15 Copper	24 Arsenic	30 Mercury	38 Glucium
2 Sodium	9 Iron	16 Lead	25 Molybdenum	31 Silver	39 Zirconium
3 Lithium	10 Zinc	17 Antimony	26 Chromium	32 Gold	40 Yttrium
4 Calcium	11 Tin	18 Bismuth	27 Vanadium	33 Platinum	41 Thorium
5 Barium	12 Cadmium	19 Uranium	28 Tungsten	34 Palladium	42 Aluminium
6 Strontium	13 Cobalt	20 Titanium	29 Columbium	35 Rhodium	43 Silicium.
7 Magnesium	14 Nickel	21 Cerium		36 Osmium	
		22 Lanthanum		37 Iridium	
		23 Tellurium			

* Berzelius divides the metals into two leading classes: 1. Bases of the alkalis and earths; 2. Bases of the oxides and acids. The former are distinguished by their low specific gravity, being either lighter, or but little heavier than water, and they are so easily oxidized as to decompose water at common temperatures: in this list he includes Kalium (Potassium), Natrium (Sodium), Lithium, Ammonium (the hypothetical base of ammonia), Barium, Strontium, Calcium, Magnium (Magnesium), Aluminium, Beryllium (Glucium), Yttrium, and Zirconium. The second class he subdivides into, 1. Electronegative metals; that is, such as in combination with oxygen have a greater tendency to form acids, than oxides or salifiable bases; these are Selenium? Arsenic, Chromium, Molybdenum, Wolframium (Tungsten), Antimony,

Tellurium, Tantalum (Columbium), Titanium, Osmium, and Gold. 2. Electropositive metals, or such as in combination with oxygen especially produce salifiable bases: these are Platinum, Iridium, Rhodium, Palladium, Silver, Mercury, Uranium, Copper, Bismuth, Tin, Lead, Cadmium, Zinc, Nickel, Cobalt, Iron, Manganese, Cerium. The metals of the two last divisions are all more than four times heavier than water, very few of them are oxidized at common temperatures either by air or water, and their oxides are reduced by charcoal at high temperatures, and by potassium, at a moderate heat. See also Thenard (*Traité de Chimie*), and an essay on the action of the vapour of water, at high temperatures, on the metals and their sulphurets, by M. V. Regnault (*Ann. de Ch. et Ph.*, Lxii. 337).

§ I. POTASSIUM.

POTASSIUM (or Kalium of the German chemists) was discovered in 1807 by Sir Humphry Davy (*Phil. Trans.*, 1808). He obtained it by submitting hydrate of potassa, or caustic potash, to the decomposing action of Voltaic electricity: the metal was slowly evolved at the negative pole. By this process, however, it could only be procured in very minute quantities; and various other methods have been devised. The following is that described by Gay Lussac and Thenard (*Recherches Physico-chymiques*).

A sound and perfectly clean gun-barrel is bent, as shown in the annexed sketch (fig. 270). It is then covered with an infusible lute between the letters o and E, and the interior of the luted part is filled

with clean iron-turnings. Pieces of fused potassa are then loosely placed in the barrel between E and C. A A is a copper tube and small receiver, which are adapted to the extremity o, and to each other, by grinding. This apparatus is next transferred to the furnace, arranged as shown in fig. 271, x and t representing two glass

tubes dipping into mercury. The furnace is supplied with air by a good double bellows entering at B, and a small wire basket, G, is suspended below the space E C.

The part of the barrel in the furnace is now cautiously raised to a white heat, and the escape of air by the tube x shows that all is tight. Some burning charcoal is then put at the end E, of the cage G, which causes a portion of potassa to liquify and fall into the lower part of the barrel upon the iron. Hydrogen gas instantly escapes by the tube x, and attention must now be had to keep the copper tubes A A cool, by laying wet cloths upon them. When the evolution of gas ceases, fresh charcoal is placed under the potassa, and so on till the whole has passed down; if too much potassa be suffered to fall at once, the extrication of gas at x will be very violent, which should be avoided. If the space between A and o should become stopped by potassium, gas will issue by the tube t (which must always be under a greater pressure of mercury than the tube x), and the potassium must be cautiously fused by applying hot charcoal to the copper tube, when the gas will again appear at x and cease at t. When the operation is concluded, the tubes x and t are

removed, and corks quickly applied to the holes; and when the apparatus is cool, the barrel is carefully removed from the furnace, and a little naphtha suffered to run through it. The potassium is found in globules in the tube and receiver A A, and considerable portions often lodge at o. The success of this operation is certain, if the heat has been sufficient: but the barrel, if not very carefully covered with lute, is apt to melt, and much, if not the whole, of the product is lost.

Besides the above, there are other methods of obtaining potassium. M. Brunner (*Quarterly Journal*, xv. 379) employs a spheroidal wrought-iron bottle, of a capacity between a pint and a quart, and a piece of gun-barrel of the annexed shape is fitted to its neck by grinding at the end A. When this bottle is charged and well luted it is placed in a proper furnace, nearly perpendicularly, and so that the greater part of the tube may be exposed to heat (it being protected by coils of iron-wire rolled round it), while the end B projects, and has attached to it a copper receiver with a small safety-tube. This receiver, when in use, is about half filled with naphtha, and kept cold by ice or cold water. The bottle is charged with four ounces of fused caustic potassa, introduced, in small portions, alternately, with 6 ounces of clean iron-turnings broken in a mortar, and 1 ounce of powdered charcoal; and this mixture is covered by 2 ounces more of iron-turnings: it is then placed in a furnace, and a glass tube inserted into the protruding barrel at B. As soon as the whole acquires a bright red-heat, inflammable gas is evolved, which burns with a violet flame, and shortly after the green vapour of potassium is seen in the glass tube, which is then removed, and the copper receiver substituted, so that the end B may dip into the naphtha. When the evolution of gas ceases, the fire is extinguished, and the receiver carefully removed. A very successful result furnished 150 grains of potassium, in small globular masses. In another experiment the mixture in the retort consisted of 8 ounces of pure and fused carbonate of potassa, 6 of iron-turnings, finely bruised, and 2 of charcoal: from these, 140 grains of potassium were obtained. Calcined tartar was also sometimes employed instead of other forms of potassa.

The theory of these operations is by no means clearly understood in its minute details. When pure hydrate of potassa is employed in the gun-barrel experiment, more than a fourth of its weight of potassium is never obtained; the remainder is chiefly found partly undecomposed and partly in combination with the produced oxide of iron, forming a hard brittle compound, difficultly acted on by water. The evolution of potassium is evidently dependent upon the attraction of the iron at a high heat for oxygen; the water of the potassa is at the same time decomposed, and possibly the nascent hydrogen may perform its part in the reduction: the readiness with which potassium assumes the elastic state at high temperatures also contributes to its evolution; yet, when the exceedingly powerful attraction of potassium for oxygen is considered, the process is, as to its theory, obscure.

Obtained by the aid of charcoal, potassium generally contains a little carbon, which may be separated by redistilling it in a small iron or even

glass retort, with its beak dipped into naphtha, but this is a troublesome process, and generally attended by some loss of the metal.

Wöhler has described a modification of the potassium apparatus, and a peculiar receiver for its condensation, contrived by Berzelius, of which a description will be found in the twenty-second volume of the *Quarterly Journal*, p. 206. He employs carbonate of potassa produced by calcining tartar, and uses charcoal as the reducing agent. In all these arrangements it is a point of importance to have the tubes, through which the metal passes into the naphtha, as short as possible, and of a sufficient diameter, otherwise they are apt to become plugged up*. The process for obtaining potassium usually followed in Germany is described by Mitscherlich, (*Elements of Chemistry*,) and also by Graham: a mixture of calcined tartar and coarsely powdered charcoal is employed, which is heated in an iron bottle.

Potassium is a blueish-white metal of great lustre. It instantly tarnishes by exposure to air, and is gradually converted into an oxide. At 60° it is malleable, and of the consistency of wax. Its specific gravity is about 0.865. It is most conveniently preserved in naphtha, either by immersing it in that liquid, or by dipping the pieces of metal into it, and keeping them thus varnished, in a small well-stopped phial. When used, the exterior must be wiped with blotting-paper, or scraped; or the naphtha may be driven off by a gentle heat. At 150° it enters into perfect fusion; and at a bright red heat, in close vessels, it boils, and rises in green vapour. At 32° it is a hard and brittle solid, of a crystallized texture. If heated in air, it burns with a brilliant purple flame. It is an excellent conductor of electricity and of heat, and its lustre is well shown by fusing it under naphtha upon a piece of crown-glass, to which it will adhere, and through which it is seen as brilliant as mercury.

POTASSIUM AND OXYGEN. PROTOXIDE OF POTASSIUM. POTASSA. ($po + o$) or P. (Potassium is represented by the German chemists by the symbol K, from *kalium*, the name by which they have chosen to designate the metal, instead of adopting the term potassium applied to it by its discoverer. Potassa they represent by KO or K.)

* During the distillation of potassium from a mixture of carbonate of potassa and charcoal, a gray compound distils over, which, by the action of water, yields a yellow solution, from which crystals may be obtained by evaporation: these consist of potassa in combination with a peculiar acid, which from the yellow colour of its salts has been called *croconic acid*. To obtain this acid the purified crystals of croconate of potassa are powdered and put into absolute alcohol, to which sulphuric acid (sp. gr. 1.78) is carefully added, so as barely to saturate the alkali. The yellow alcoholic solution is then poured off the precipitated sulphate of potassa, and the croconic acid obtained by evaporation. It is soluble in water, and yields prismatic crystals

of a yellow colour, astringent taste, and which redden litmus: it is not decomposed at a heat of 212° , but at high temperatures it deposits pure charcoal. Gmelin considers this acid as a compound of 5 atoms of carbon and 4 of oxygen, with apparently a small proportion of hydrogen, which, however, is less than 1 atom.

Anhydrous croconate of potassa is yellow and opaque; its crystals are orange-coloured prisms, transparent, inodorous, tasting like saltpetre; moderately soluble in cold, and very soluble in hot water, and insoluble in absolute alcohol: heated nearly to redness the salt suddenly glows throughout, rapidly evolving carbonic acid with a little carbonic oxide, and leaving a residue of carbonate of potassa and charcoal.

The attraction of potassium for oxygen, under most circumstances, exceeds that of all other bodies; it is consequently one of the most powerful deoxidizing agents which we possess. It forms two definite compounds with oxygen, which we may call the *protoxide* and *peroxide*; Berzelius admits a *suboxide*, but it is probably a mixture of potassium with the protoxide. When potassium is thrown upon water it takes fire, hydrogen gas is evolved, and a solution of *protoxide of potassium*, or *potassa*, is formed. When plunged under water, the potassium decomposes it with explosive violence, but without ignition, and the volume of the hydrogen evolved may be assumed as the equivalent or indicator of the proportion of oxygen transferred to the metal; 100 parts of potassium are thus found to absorb 20 of oxygen; and if this be considered a protoxide, then 20 : 100 :: 8 : 40,—so that 40 will be the number representing potassium (39·3 GRAHAM, 39·15 TURNER), and the *protoxide* or *potassa*, in its dry or anhydrous state, consists of

				Berzelius.	Davy.	Gay Lussac and Thenard.
Potassium	1	40	83·33	83·05	85	83·371
Oxygen	1	8	16·67	16·95	15	16·629
Potassa	1	48	100·00	100·00	100	100·000

The equivalent of potassium, deduced from the analysis of the chloride of potassium by Berzelius, is 39·15; he also states that 100 of potassium combine with 20·412 of oxygen; so that upon these data, the equivalent of potassium would be between 39 and 40. Mr. F. Penny, in his paper "on the application of the conversion of chlorates and nitrates into chlorides, and of chlorides into nitrates, to the determination of several equivalent numbers," arrives at the conclusion that 39·08 is the equivalent of potassium. (*Phil. Trans.*, 1839, p. 13.)

Potassa, in the state it is usually met with in laboratories under the name of *caustic potash*, contains a considerable portion of water, as is rendered manifest by the action of iron upon it at high temperatures, which occasions the evolution of hydrogen; and there always remains in the gun-barrel, after the above-described experiment, a portion of *dry potassa* combined with oxide of iron. To obtain dry potassa, or *anhydrous protoxide of potassium* in its pure state, the metal may be exposed, at common temperatures, to the action of perfectly dry air or oxygen; or 1 part of potassium may be fused with 1·4 of hydrate of potassa. It is a gray substance, fusible at a red heat, and volatile when heated to whiteness in the air. It combines very energetically with water to produce a *hydrate*, and what is commonly called *pure potassa*, is, in fact, this hydrate, composed of

Hydrate of potassa	1			57		100.0	100

HYDRATED PROTOXIDE OF POTASSIUM, OR CAUSTIC POTASSA, (P+Q,) is procured in our laboratories by decomposing carbonate of potassa by lime. The best process consists in boiling in a clean iron vessel pure carbonate of potassa, with half its weight of pure quick-lime, in six or eight parts of water. The lime, which may be previously slaked, is

gradually added to the boiling alkaline solution, which is kept constantly stirred, and towards the end of the operation it is tested, by filtering a small portion, and pouring it into three or four times its bulk of dilute nitric acid: if there be no effervescence, sufficient lime has been used; but if carbonic acid escapes, the ebullition with lime must be continued until the tested portion shows no signs of carbonic acid. The whole is then allowed to remain quiet, that the carbonate of lime and excess of the hydrate of lime may subside; the clear liquor or *ley* may then be siphoned off, concentrated by evaporation, strained through a clean calico filter, and set by in a well-stopped bottle till it admits of being decanted, perfectly clear from any sediment. The clear solution is to be evaporated in a polished iron or pure silver basin, till it assumes the appearance of an oily liquid and concretes on cooling. It is often cast into sticks for the use of surgeons, who employ it as a caustic, and in this state it generally contains some peroxide and other impurities, and evolves oxygen and deposits a sediment when dissolved in water. It is the *potassa fusa* of the *London Pharmacopeia*. Having obtained the fused caustic potassa by lime, it may be further purified by boiling it in a silver basin with highly-rectified alcohol for a few minutes, and then setting it by in a stopped phial; when the impurities are deposited, the alcoholic solution may be poured off and rapidly evaporated to dryness in a silver vessel; or if the quantity of alcohol be considerable, it may be distilled off in a silver alembic with a glass head: the heat may then be raised so as to fuse the potassa, which on cooling should be broken up and preserved in well-closed phials.

Thus purified, hydrate of potassa is white, somewhat crystalline in texture, very acrid and corrosive, fusible at a heat below redness, and evaporates from an open vessel, at a bright-red heat, in the form of acrid fumes. At a white heat it is decomposed by charcoal, and carburetted hydrogen, carbonic oxide, and potassium, are formed. It quickly absorbs moisture and carbonic acid from the air, and is soluble in half its weight of cold water. When reduced to powder and slightly moistened it forms a crystallized combination which is said to be a terhydrate ($P + 3q$). By keeping a strong aqueous solution of potassa at a low temperature in a stopped phial, octoëdral and tabular crystals may be obtained which are stated to be a definite pentahydrate ($P + 5q$). It is highly alkaline, powerfully reddening turmeric, and converting several vegetable blues to green: and by a strong solution of it these colours are almost destroyed. It also acts energetically upon the greater number of organic products, and unites with the fat oils to form soap, hence the term *soap-lye*. Being generally and indeed almost exclusively procured from vegetables, it was formerly called *vegetable alkali*; but it also exists in certain minerals, and in a few animal secretions. Fuchs says that it may be economically obtained from certain varieties of felspar: for this purpose they are calcined with lime, then left for some time in contact with water, and the liquor filtered and evaporated. He says he has thus procured 19 per cent. from felspar and 15 from mica. When touched with moist fingers caustic potassa has a soapy feel, in consequence of its action upon the cuticle, and it then exhales a peculiar odour; this is also perceptible in the solution of potassa, and is probably referable to traces of organic matter acci-

dentally present. In the fused state it produces heat when dissolved in water; but in its crystallized state it excites considerable cold, especially when mixed with snow. At a natural temperature of 30° , Lowitz found that equal weights of crystallized potassa and snow depressed the thermometer 45° . (*Ann. de Chim.*, xxii.) It dissolves sulphur and several sulphurets, and alumina and silica. The oxides of manganese, zinc, tin, lead, antimony, cobalt, arsenic, molybdenum, tungsten, and nickel, are also soluble in aqueous solution of potassa.

The *Liquor Potassæ* of the Pharmacopœia is directed to be prepared as follows:—"Take of carbonate of potassa 15 ounces, lime 8 ounces, boiling distilled water a gallon. Dissolve the carbonate in half a gallon of the water; sprinkle a little of the water upon the lime in an earthen vessel, and the lime being slaked add the rest of the water. The liquors being immediately mixed together in a close vessel, shake them frequently until they are cold; then set the mixture by that the carbonate of lime may subside. Lastly, having poured off the supernatant liquor, keep it in a well-stoppered green glass bottle." Its specific gravity is 1.063.

Whilst a solution of caustic potassa is filtering, it is apt to absorb a little carbonic acid from the air, which may be prevented, upon the small scale, by covering the funnel with a plate of glass, and receiving it into a bottle as nearly air-tight as possible; or the annexed filtering apparatus, fig. 273, contrived by Mr. Donovan (*Annals of Philosophy*, xxvi. 115), may be used. It consists of two glass vessels connected by a tube, made air-tight by perforated corks at the junctions *a* and *b*. The upper vessel containing the solution to be filtered, terminates in a conical pipe, ground into the lower one, and into which is stuffed a piece of coarse linen.

In all cases where solutions of potassa are employed, it must be recollected that they gradually act upon glass, especially upon common white glass; hence green glass vessels are preferable: but where alkaline solutions are to be exposed to heat, or evaporated to dryness, even these communicate some impurity, and in such cases vessels of pure silver can only be relied upon, for they exert more or less action upon almost all the other metals, platinum not excepted.

The solution of caustic potassa is also frequently impure from the presence of carbonic acid, silica, alumina, lime, and sulphuric or hydrochloric acid. If nitric acid cause an effervescence when dropped into it, it indicates *carbonic acid*; if a gelatinous precipitate, not soluble in very slight excess of acid, it is *silica*; if soluble, it is *alumina*. The presence of *lime* is shown by adding oxalate of ammonia to the solution previously neutralized by nitric acid: in the same solution, nitrate of silver will indicate hydrochloric acid, or *chlorine*, and nitrate of baryta, *sulphuric acid*, or *sulphates*.

It may sometimes be useful to know the quantity of real potassa contained in watery solutions of different specific gravities; the following are the results of Dalton's experiments, in reference to this question:—

Specific Gravity.	Potassa per Cent.	Boiling Point.	Specific Gravity.	Potassa per Cent.	Boiling Point.

PEROXIDE OF POTASSIUM. ($p + 3o$).—When potassium is burned in a silver spoon in oxygen gas, a yellow fusible substance is obtained, which, on cooling, acquires a scaly crystalline appearance. It consists, according to Gay Lussac and Thenard, of

				Gay Lussac and Thenard.
Potassium	1	40	62.5	65
Oxygen	3	24	37.5	35
Peroxide of potassium	1	64	100.0	100

This substance has some singular properties; it supports the combustion of most of the inflammables, and when heated in hydrogen, diminishes the bulk of the gas, and forms water: it decomposes ammonia under the same circumstances. When put into water, oxygen gas is evolved, and a solution of potassa obtained. When hydrate of potassa is fused in an open crucible, a portion of its water is disengaged, and oxygen absorbed, so as to form this peroxide; and hence it is, that common caustic potassa almost always effervesces, and gives out oxygen upon the affusion of water. When potassium is dropped into melted nitre, the peroxide is also formed; likewise by passing oxygen over potassa heated to redness.

POTASSIUM AND CHLORINE. CHLORIDE OF POTASSIUM. ($po + c$) or KCl.—Potassium burns brilliantly in chlorine, especially if introduced into the gas in the state of fusion, as, otherwise, a crust of chloride is apt to form and protect the interior from further action. This compound, formerly called *muriate of potash*, consists of

				Ure.
Potassium	1	40	52.6	53
Chlorine	1	36	47.4	47
Chloride of potassium	1	76	100.0	100

When potassium is heated in gaseous hydrochloric acid, chloride of potassium is formed, and hydrogen evolved; an experiment already adverted to under the article *Hydrochloric Acid* (p. 396). It is also formed by dissolving potassa or its carbonate in hydrochloric acid, and evaporating to dryness.

Chloride of potassium dissolves in three parts of water at 60°, or, according to Gay Lussac, 100 parts of water at 32° dissolve 29.23, and for every 1.8° above 32, the water takes up 0.2738 more of the salt. One part of the powdered salt stirred into four parts of cold water produces a depression of temperature of between 20° and 25°, whereas chloride of sodium under the same circumstances only depresses the ther-

mometer between 2° or 3° , hence it has been proposed to estimate the relative proportions of these chlorides when mixed, by the depression of temperature resulting from their solution. Chloride of potassium crystallizes in cubes, which are anhydrous; its taste is saline and bitter. In old pharmacy it was called *digestive salt of Sylvius*; also, *regenerated sea-salt*. It is insoluble in alcohol. When intensely heated in open vessels, it evaporates in the form of white fumes. This salt is a residue of several chemical and pharmaceutical processes, and is sometimes found in considerable quantities in rough salt-petre, where it is often mistaken for common salt; it is also contained in kelp: the manufacturers of alum occasionally employ it as the source of potassa in that salt.

CHLORATE OF POTASSA $(p + o) + (c + 5o)$ or $(P + c')$ or $\overset{\cdot\cdot}{\underset{\cdot\cdot}{K}} \overset{\cdot\cdot}{\underset{\cdot\cdot}{C}} \overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}_3$, is formed by passing chlorine through a solution of potassa. Chloride of potassium is one of the results, the other is *chlorate of potassa*, a salt in brilliant rhomboidal tables (formerly called *oxymuriate of potash*). Its crystalline forms have been described by Mr. Levy (*Quarterly Journal*, xv. 286), and by Mr. Brooke (*Ann. Phil.*, v. 451): they belong to the oblique prismatic system.

This salt is prepared, upon the large scale, by charging one or two Woulfe's bottles with a strong solution of carbonate of potassa, and passing chlorine slowly through it at the lowest convenient temperature: the gas is absorbed, and the liquor effervesces, chiefly from the escape of carbonic acid; when this has ceased, the liquor may be put aside in a cold dark place for about 24 hours, when it will be found to have deposited a considerable portion of the crystallized chlorate, which may be taken out, drained, and purified by solution in hot water, which, during cooling, again deposits the salt in white crystalline scales. The mother-liquor, from which more of the salt may be obtained by evaporation, is generally of a pinkish tint, from the presence of a trace of manganese; but this tint disappears when sufficiency of chlorine has been passed in to saturate it, and it acquires a brownish hue*. Solution of pure potassa absorbs the gas more readily than the carbonate, but nearly with the same phenomena, and in either case care must be taken that the tube conveying the chlorine does not become stopped up by the salt, which is apt to happen if it be not sufficiently capacious. To understand the theory of this process we must recollect that chloric acid is a compound of one proportional of chlorine and five of oxygen, and that chloride of potassium consists of one proportional of chlorine and one of potassium, and that potassa contains one proportional of oxygen and one of potassium: it follows, then, that five proportionals of chlorine acting upon five of potassa will expel five of oxygen, which, uniting with one of chlorine, will form one proportional of chloric acid, and this uniting to a proportional of undecomposed potassa will form chlorate of potassa, as shown in the following diagram:—

* In this process, the carbonic acid is expelled when excess of chlorine is passed into the solution: by particular management chlorine may be retained

in a solution of carbonated alkali, forming a peculiar compound of chlorine, or hypochlorous acid, and potassa. See *Carbonate of Soda*.

It appears, therefore, that five proportionals of potassa will require six of chlorine to be consumed in the formation of five proportionals of chloride of potassium, and one proportional of chloric acid. The elements of the water are not concerned in the formation of these products, but that fluid performs the important office of en-

abling the different elements to act upon each other in their nascent states.

According to Löwig, chloride of lime, which by long keeping has lost much of its bleaching power, contains chlorate of lime, and may be used for the preparation of chlorate of potassa: the solution of the lime salt is boiled in order to complete the conversion of the chloride into chlorate, and then partially decomposed by carbonate of potassa, or evaporated with an admixture of chloride of potassium, when chlorate of potassa crystallizes, and chloride of calcium remains in solution. (GRAHAM.)

Chlorate of potassa is an anhydrous salt of a cooling and austere taste. Its specific gravity is 1.989. (HASSENFRATZ.) When pure, its aqueous solution is not rendered turbid by nitrate of silver. When triturated, it appears phosphorescent. It decrepitates and fuses at a temperature between 400° and 500° : at a higher heat it effervesces, and gives out nearly 40 *per cent.* of its weight of oxygen, and chloride of potassium remains. It is soluble in 18 parts of cold and 2.5 of boiling water; or, according to Gay Lussac, 100 parts of water at 32° dissolve 3.5 parts, at 59° 6 parts, at 95° 12 parts, at 120° 19 parts, and at 216° , which is the boiling-point of the saturated solution, 60 parts. It acts very energetically upon many inflammables, and triturated with sulphur, phosphorus, and charcoal, produces inflammation and explosion. A mixture of three parts of this chlorate with one of sulphur, detonates loudly when struck upon an anvil with a hammer, and even sometimes explodes spontaneously; hence it should not be kept ready mixed. Chlorate of potassa was proposed by Berthollet as a substitute for nitre in gunpowder. The attempt was made at Essone in 1788: but, as might have been expected, no sooner was the mixture of the chlorate with the sulphur and charcoal submitted to trituration, than it exploded with violence, and proved fatal to several persons. With phosphorus the detonation is dangerously violent; the experiment is best made, by wrapping a grain of phosphorus and two of the chlorate in a small piece of paper, and striking them a blow with a hammer, upon an anvil. The phosphorus is generally thrown about in an inflamed state. These phenomena depend upon the sudden decomposition of the chloric acid.

The action of sulphuric acid upon chlorate of potassa has already been adverted to. (See *Peroxide of Chlorine*, p. 368.) If, instead of distilling the yellow mixture of the acid and chlorate with the caution there described, it be heated to about 212° , it suddenly explodes. The theory of the production of chloric oxide is more explicitly described in the next article.

When sulphuric acid is dropped upon mixtures of this salt and combustibles, instant ignition ensues in consequence of the evolution of per-

oxide of chlorine. A mixture of sugar and the chlorate thus treated, is immediately kindled, with a red and blue flame; and a mixture of sulphuret of antimony and the salt suddenly deflagrates with a bright puff of flame and smoke: the latter mixture requires to be cautiously made, as it often takes fire by mere trituration. Matches tipped with some of these inflammable mixtures, and called *Lucifers*, are now in common use, and are inflamed either by friction or by the contact of sulphuric acid, which is most conveniently applied by putting some asbestos into a small well-stopped phial, and moistening it with sulphuric acid; the match is rapidly dipped into the phial and inflames on touching the asbestos, without the risk of spirting about the acid. Some of the matches which inflame by a pinch or blow, contain a portion of a drop of sulphuric acid hermetically sealed in a piece of very small and thin glass tube, and which escapes when broken, and acts upon the inflammable mixture. Berzelius gives the following as the best composition for the match: 30 parts of powdered chlorate of potassa, 10 of powdered sulphur, 8 of sugar, 5 of gum-arabic, and a little cinnabar. The sugar, gum, and salt, are first rubbed together into a paste with a sufficiency of water; the sulphur is then added, and the whole being thoroughly beaten together, small brimstone matches are dipped in, so as to retain a thin coat of the mixture upon their sulphuretted points: they should be quite dry before they are used. Some of the recently-improved lucifer matches appear to contain phosphorus; they inflame by slight friction upon emery paper or any hard rough substance. One of the compounds occasionally employed in percussion gun-locks is a similar composition: 10 parts of gunpowder are rubbed with water, and the soluble part poured off; the remaining paste is then mixed with $5\frac{1}{4}$ parts of finely-powdered chlorate of potassa, and a drop of it put into each of the small copper caps adapted to the peculiar tubular touch-hole of the gun; a blow being struck upon the cap the powder is inflamed, and communicates to that in the barrel. The great disadvantage of this compound is, that it forms products which soon rust the touch-hole and surrounding parts: fulminating mercury is, therefore, now generally substituted.

When sulphuric or nitric acids are poured upon mixtures of chlorate of potassa and certain combustibles under water, by means of a long funnel, inflammation also ensues. In this way a beautiful experiment may be made with phosphorus, a few small pieces of which are put at the bottom of a tall glass of water, and a little of the chlorate thrown in upon it; sulphuric acid is then carefully introduced into the contact of the salt by a funnel, with a tube long enough to reach to the bottom of the glass; the phosphorus presently inflames and burns vividly in different parts of the fluid, forming a kind of well of fire. A few grains of chlorate of potassa put into a teaspoonful of hydrochloric acid, and then diluted with water, form an extemporaneous bleaching-liquor.

The ultimate elements of chlorate of potassa are

OXYCHLORATE OR PERCHLORATE OF POTASSA ($p+o$) + ($c+7o$) or ($P+c''$) or $\overset{\cdot\cdot\cdot}{\text{K}} \overset{\cdot\cdot\cdot}{\text{C}}$, may be formed by moistening one part of chlorate of potassa with three of sulphuric acid, and subsequently *carefully* warming the mass till it becomes white, and the oxide of chlorine is expelled: in this state it consists of bisulphate and perchlorate of potassa, which may be separated by solution and crystallization, the former being much more soluble in cold water than the latter salt.

In reference to the production of peroxide of chlorine and perchloric acid, as the result of the action of sulphuric acid upon chlorate of potassa, the annexed diagram may, perhaps, be useful. The original substances are printed in capitals, the components in common type, and the resulting compounds in italics; the volumes of oxygen and of chlorine being shown by the usual symbols of bulks which I have elsewhere employed. The Roman numerals denote the number of proportionals or equivalents presumed to be employed or formed.

Thus it appears that 6 proportionals of sulphuric acid acting upon 3 of chlorate of potassa form 3 of bisulphate of potassa, and detach 3 of chloric acid, the elements of which are 3 of chlorine and 15 of oxygen: of these, 2 proportionals of chlorine and 8 of oxygen form 2 of peroxide of chlorine; and the remaining 1 of chlorine and 7 of oxygen form perchloric acid. If instead, as in the above diagram, of considering the mere formation of perchloric acid, we refer to the formation of perchlorate of potassa, we must assume that the oxygen is transferred to the chloric acid of an undecomposed portion of chlorate of potassa, and so converts it into perchlorate.

Perchlorate of potassa does not change vegetable colours, nor is it altered by exposure to air. It crystallizes in small octoëdra with square bases. It requires rather more than 50 parts of water at 60° for its solution: but is much more soluble in boiling water. It is insoluble in alcohol: it detonates slightly when rubbed with sulphur. When mixed with its own weight of sulphuric acid, and distilled at 280°, solution of oxychloric acid passes over. It may be decomposed by exposure to a temperature of 412°. Oxygen is given off, equal to 0·45 per cent. of the weight of the salt, and chloride of potassium remains in the retort.

Gmelin states that when a saturated solution of chlorate of potassa is exposed to the decomposing agency of Voltaic electricity, transmitted by platinum poles, crystals of oxychlorate of potassa are formed at the positive pole, whilst hydrogen is evolved at the negative.

IODIDE OF POTASSIUM. (*po + i*) or K I.—Iodine and potassium act upon each other very energetically, evolving heat and light, and a crystalline compound is obtained, white and fusible. When hydriodic acid is saturated by potassa, and the solution carefully evaporated, anhydrous prismatic crystals of the iodide (or as it is sometimes called *hydriodate of potassa*) are obtained. The readiest mode of procuring this compound consists in dissolving iodine in solution of potassa, till it begins to assume a brown colour; on evaporating to dryness, and fusing the residuary salt, a pure iodide of potassium remains. If, instead of fusing the products, the solution be carefully evaporated nearly to dryness, and alcohol poured upon it, the iodide is dissolved, and there remains a salt insoluble in alcohol, which is *iodate of potassa*, and which, at a red heat, evolves oxygen, and becomes iodide of potassium. The action of iodine upon the alkali appears in all respects to correspond with that of chlorine. Iodide of potassium is also frequently prepared by decomposing a solution of iodide of zinc by carbonate of potassa, and filtering off and evaporating the resulting solution of the iodide, which, however, is apt to retain iodide of zinc. The Pharmacopœia directs the decomposition of a solution of iodide of iron by carbonate of potassa, but in this case all traces of iron are very difficultly got rid of. Iodide of potassium forms cubic and prismatic crystals, which are deliquescent in very damp air. According to Gay Lussac, 100 parts of water at 65° dissolve 143 of this salt, and a considerable depression of temperature is produced during the solution; it is sparingly soluble in absolute alcohol, but much more so in alcohol, sp. gr. 850. It is pretty largely used in medicine, and as it occurs in commerce is frequently mixed with chloride of potassium and sodium,

and with sulphate and carbonate of potassa. It should be purchased in crystals, which ought not to be very deliquescent, and should perfectly dissolve in six or eight parts of alcohol, sp. gr. '836. They generally redden turmeric from the presence of a little adhering carbonate of potassa.

Iodide of potassium consists of

Potassium	1	40	24	Gay Lussac. 23·8
Iodine	1	126	76	76·2
<hr/>		<hr/>	<hr/>	<hr/>
Iodide of potassium	1	166	100	100·0

The aqueous solution of iodide of potassium dissolves a considerable portion of iodine; this solution, under the name of *ioduretted iodide of potassium*, is sometimes used in medicine: it is of a deep-brown colour. According to Baup a saturated solution of iodide of potassium will dissolve two equivalents of iodine, one of which falls on diluting the solution.

IODATE OF POTASSA $(p+o) + (i+5o)$ or $P+i'$, obtained as just described, is a white, difficultly soluble salt, requiring about 14 parts of water at 60° for its solution: at a red heat, it gives out between 22 and 23 *per cent.* of oxygen, and is converted into iodide of potassium. Iodide of potassium may also be converted into iodate of potassa, by fusing it in a crucible, and projecting upon it rather less than twice its weight of chlorate of potassa: warm water removes the chloride of potassium and leaves the iodate.

This salt is insoluble in alcohol: it forms small and permanent prismatic crystals, soluble without decomposition in warm sulphuric acid, and detonating with a purple flame when thrown upon hot coals. With the addition of potassa, it yields a crystallizable subsalt, the exact composition of which has not been determined; it is very soluble.

Iodate of potassa consists of

Potassa	1	48	22·54
Iodic acid	1	166	77·46
<hr/>		<hr/>	<hr/>
Iodate of potassa	1	214	100·00

Serullas has described a *biniodate* and a *teriodate* of potassa. (*Ann. de Ch. et Ph.*, xliii. 113.) The biniodate is obtained by adding an additional equivalent of iodic acid to a solution of the neutral iodate saturated at a high temperature: it forms prismatic crystals with diëdral summits, which retain an equivalent of water, but which, according to Graham, may be rendered anhydrous by heat: it is soluble in 75 parts of water at 60° . The *teriodate* is formed when a strong acid is added to a hot saturated solution of the neutral iodate, and allowing it to cool slowly: it forms rhomboëdral crystals soluble in 25 parts of water. According to Serullas the biniodate of potassa has a great tendency to form double salts; one of these, with *chloride of potassium*, is obtained in crystals, when a little hydrochloric acid is added to a solution of iodate of potassa and the mixture subjected to spontaneous evaporation: it contains 1 atom of the biniodate with 1 of chloride; it cannot be formed by the direct union of its component salts, and is decomposed by water. Another double salt of biniodate with *bisulphate of potassa* is obtained from the mother liquor

which remains when teriodate of potassa is prepared by means of sulphuric acid; it forms crystals which are decomposed by water, and, like the preceding, cannot be formed directly.

BROMIDE OF POTASSIUM. ($po + b$) or K B.—Potassium and bromine act intensely upon each other, evolving heat and light, and producing explosion. When bromine is dropped into solution of potassa, the mixture evaporated, and the residue heated to redness, *bromide of potassium* is also obtained; it is white, fusible, and crystallizes in cubes, easily soluble in water, and slightly so in alcohol. It consists of

Potassium	1	. .	40	. .	33.9
Bromine	1	. .	78	. .	66.1
<hr/>						
Bromide of potassium		1		118		100.0

It is prepared for medical use, either by the above process, or by decomposing bromide of zinc or bromide of iron, by carbonate of potassa; it should be purchased in crystals, as it is otherwise apt to be impure.

When ethereal solution of bromine is agitated with liquid potassa, the yellow colour disappears, and bromate of potassa and bromide of potassium are the results. The action, therefore, of bromine is here analogous to that of chlorine and iodine.

BROMATE OF POTASSA ($po + o$) + ($b + 5o$) or ($P + b'$) separates in the form of a crystalline powder, when bromine and solution of potassa are mixed in sufficient quantities. It scintillates on a hot coal, like nitre, and evolving oxygen becomes bromide of potassium. It is slightly soluble in alcohol, readily soluble in water, and crystallizes in needles: mixed with sulphur it detonates by a blow. Its solution occasions a white precipitate in nitrate of silver. (BALARD, *Quarterly Journal*, xxii. 389.)

FLUORIDE OF POTASSIUM. ($po + f$).—When hydrofluoric acid is saturated with potassa, and evaporated to dryness, a deliquescent and very difficultly crystallizable compound is obtained, which must be regarded as a *fluoride of potassium*. It probably consists of

Potassium	1	. .	40	. .	68.965
Fluorine	1	. .	18	. .	31.034
<hr/>						
Fluoride of potassium		1		58		100.000

This fluoride bears an intense heat without change.

Berzelius has described an apparently peculiar compound, obtained by dissolving the above fluoride in hydrofluoric acid, and evaporating to dryness in a platinum vessel: it is crystallizable, readily soluble in water, and when heated to incipient redness is decomposed, hydrofluoric acid being evolved, and fluoride of potassium remaining. It appears to consist of

						Berzelius:

POTASSIUM AND HYDROGEN.—When potassium is heated in hydrogen, it absorbs a portion of the gas, and produces a gray infusible *hydruret*,

destitute of lustre, and burning vividly when heated in air or oxygen gas. When heated, *per se*, it evolves hydrogen; and the same change takes place in the contact of mercury. When hydrogen and potassium are passed together through a white-hot tube, the gas dissolves the metal, and produces a spontaneously inflammable *potassiuretted hydrogen gas*. Potassiuretted hydrogen is also produced when potassium is thrown upon water, and is the cause of the red flame and white fumes produced during its combustion under such circumstances. Both these compounds are usually formed during the operation for obtaining potassium by the gun-barrel. (GAY LUSSAC and THENARD.)

NITRATE OF POTASSA. NITRE. SALTPETRE. $(po + o) + (n + 5o)$ or $(P + n')$, or $KO NO_5$, or $K \ddot{N}$.—This salt is an abundant natural product, and is principally brought to this country from the East Indies, where it is produced by lixiviation from certain soils. The greater part of the rough nitre imported from the East Indies is in broken crystals of a brown colour, and more or less deliquescent; exclusive of other impurities, it often contains a very considerable portion of common salt, which, re-acting upon the nitre, induces the production of a portion of nitrate of soda and chloride of potassium. It also usually contains sulphate of lime, and often evident traces of organic matter.

In Germany and France it is artificially produced in what are termed nitre-beds. Thenard (*Traité de Chimie Élémentaire*) has described the French process at length. (See also DUMAS, *Chim. App. aux Arts*, ii., and KUHLMAN, *Mem. Acad. Sciences de Lille*, 1838; also LIEBIG's *Ann.*, xxix. 272.) It consists in lixiviating old plaster rubbish, which, when rich in nitre, affords about five per cent. Refuse animal and vegetable matter, which has putrified in contact with calcareous soils, produces nitrate of lime, which affords nitre by mixture with carbonate of potassa. In the same way it is abundantly produced in some parts of Spain. Exudations, containing saltpetre, are not uncommon upon new walls, where it appears to arise from the decomposition of animal matter contained in the mortar. It was long ago shown by Glauber, that a vault plastered over with a mixture of lime, wood-ashes, and cows' dung, soon becomes covered with efflorescent nitre, and that, after some months, the materials yield, on lixiviation, a considerable proportion of that salt.

The loss which rough nitre sustains in refining, is technically termed the *refraction*, and can only be ascertained by analysis, which frequently is somewhat difficult and intricate: it is, moreover, not easy to get a fair sample of a cargo. The samples which the merchants and brokers select for analysis, generally consist of portions drawn from each bag and afterwards mixed together, and if carelessly or unfairly taken, or exposed so as to become more moist or more dry than the bulk, the report of the analyst is often unsatisfactory. He should work upon not less than 25 to 50 lbs. of such sample, which should be ground or triturated so as to produce a properly uniform mixture of the whole, for it often includes lumps of pure nitre or of other salts; of this uniform mixture a portion is then taken for analysis. The moisture is determined by the loss occasioned by drying a given weight on the sand-bath. A portion is then dissolved

in water and tested, so as to acquire some general notion of the impurities; and, from the effect of nitrate of silver, nitrate of baryta, and oxalate of ammonia, the presence of chlorides, sulphuric acid, and lime, is determined: the lime is generally in the state of sulphate, and more or less sulphate of potassa is also usually present; the chlorine is chiefly derived from the chlorides of potassium and sodium. Another portion of the sample should be dissolved in about thrice its weight of boiling water, and filtered, by which the sand and other insoluble impurities are collected; the salt should then be crystallized in the usual way, during which the appearances and forms of the successive deposits will indicate, to the experienced eye, the nature of the foreign salts present; among which nitrate of soda, sulphate of potassa, sulphate and nitrate of lime, and chloride of sodium and potassium, with traces of chloride of calcium, and sometimes of a peculiar organic matter, are frequently found. It will be obvious that the accurate quantitative analysis of such a mixture of salts is not a very easy problem, and yet the separation of nitrate of soda from nitrate of potassa, and of chloride of potassium from chloride of sodium, are essential steps, inasmuch as the value of the sample is materially affected by their relative proportions: for nitrate of soda, to say nothing of its unfitness for the manufacture of gunpowder, is cheaper than nitrate of potassa; and chloride of sodium is of no value, whilst chloride of potassium is purchased by the alum-makers; so that a sample of nitre, containing the latter salt, is in this respect worth more than where it only contains common salt. But inasmuch as the equivalent of chloride of sodium is only 60, and that of chloride of potassium 76, it is obvious that if the whole of the chlorine, as indicated by the weight of the chloride of silver, be considered as in combination with sodium (part of the sample consisting of chloride of potassium), the refraction will be estimated below the mark. Hence the necessity of ascertaining the relative proportions of both chlorides, which is best effected by converting them into sulphates, and separating them by crystallization.

A rough method of determining the value of a sample of nitre, and which, in some cases, especially where common salt is the chief impurity, admits of considerable accuracy, consists in putting a pound of the salt in powder into a basin, and pouring upon it a pint of a saturated aqueous solution of pure nitre; this mixture is well stirred for 15 or 20 minutes, then left at rest, and when the salt is deposited, the liquor is poured off and filtered: half a pint of the saturated solution of pure nitre is then again poured upon the remaining salt, stirred as before, and then the whole contents of the basin are carefully transferred into the filter. In some cases where the quantity of common salt is excessive (exceeding 66 per cent.) the washing must be repeated a third time, but this is rarely necessary. When the dripping of the filter has ceased, it is carefully removed with its contents, from the funnel, and placed upon a few sheets of coarse filtering paper lying upon a chalk table or other absorptive substance, the saltpetre being carefully spread out so that the moisture may be absorbed. When it is dry enough to admit of removal, it must be carefully transferred into a basin placed upon a sand bath, and the drying completed till it no longer adheres to the rod or ivory knife with which it is stirred; it is then weighed, and the loss of weight, (as compared

with the sample,) gives the impurities; but from this, 2 *per cent.* should be deducted for the nitre deposited by the saturated solution whilst taking up the common salt. When the common process for refining nitre is conducted as follows, it may be made subservient to the more accurate analysis.

PURIFICATION OF NITRE.—A given quantity of the rough salt (say 7 lbs.) is accurately weighed, and then dissolved by heat in three or four parts of water; when boiling, the scum is removed until no more rises, and then the solution is allowed to settle for ten minutes or longer. In this way nearly all the dirt falls down, and the clear solution, being poured off, is passed through a filter of tow into a pan, and set aside to crystallize; the dirt left behind is added to the scum, and both being diluted, are filtered through paper, and the clear solution preserved. Next day the crystals formed in the pan are separated and put into funnels to drain, and the mother-liquor with the filtered solution from the scum, &c. are further evaporated, and again left to crystallize. On the second evaporation, impurities generally separate from the solution; these are sometimes oxide of iron, or sulphate of lime, but most frequently chloride of sodium and of potassium, sulphate of potassa, and nitrate of soda. The two first are easily separated by filtration; the chlorides are best separated by evaporating the solution considerably, until much salt has been deposited, and then pouring the whole upon a filter of tow; the common salt, with more or less of the others, will remain on it, and should be washed by water to separate the nitre, which water should be added to the liquor, and the whole then brought to the crystallizing point. When cold, the crystals deposited by this solution are to be separated as before, until the mother-liquor is divided into other salts and nitre. It frequently happens that the crystals from the two or three last evaporations are coloured or contaminated by the adhesion of common salt, sulphate of lime, &c.; in this case, they should be re-dissolved and re-crystallized with the same precautions as before. Care should be taken in drying the crystals, especially when large, that no water remain in the interstices or cleavages between them, which is often the case to a considerable extent; and not unfrequently the interstitial water retains foreign salts, so that, in purifying nitre upon the large scale, it is often advantageous to stir it whilst crystallizing, that the crystals may be small and broken, and then the adhering impurities may be better washed out by cold water. When pure, the solution of nitre is not rendered turbid either by nitrate of silver or nitrate of baryta.

Nitre crystallizes in six-sided prisms, usually terminated by dièdral summits. Its specific gravity is 1.933. Its primitive form is a right rhombic prism, the measurement and modifications of which have been given by Mr. Levy (*Quarterly Journal*, xv. 284). The crystals are large and smooth when obtained from a great mass of solution, but irregular and striated when formed in smaller quantities. The large crystals are very sensible to changes of temperature, and when handled generally crack transversely; so that it is difficult to preserve them entire. They are not altered by exposure to air. According to Bergman, nitre dissolves in 7 parts of water at 60°, and in its own weight at 212°; but these proportions are not correct: La Grange states that 1 part of nitre dissolves in between 3 and 4 of water at 60°, and in half its weight at 212°. Gay

Lussac has shown that the solubility of nitre varies extremely with temperature: at 32° , 100 parts of water dissolve 13.2 of the salt; at 77° , the salt dissolved by 100 of water is 38 parts; at 132° , it amounts to 97 parts; at 176° , to 169 parts; at 210° , to 236 parts; and at 212° , to 246 parts. According to Dr. Ure, the temperature of a saturated solution of nitre, boiling hot, is 340° , and the relation of the salt to its solvent is in weight as 3 to 1. Upon the same authority, water at 60° dissolves one-fourth its weight of nitre; or, more exactly, this saturated solution contains 21 per cent. of salt: its specific gravity is 1.1415; and 100 parts in volume of the two constituents occupy now 97.91 parts. (*Jour. Royal Inst.*, i. 121.) Berzelius observes, that the solubility of nitre is apparently increased by the presence of common salt, but that this arises from their mutual reaction, producing nitrate of soda and chloride of potassium. Yet, during crystallization, common salt and nitre separate distinctly from each other. During the solution of 1 part of powdered nitre in 5 of water, the temperature sinks from 50° to 35° . Its use in cooling mixtures has already been noticed, p. 169. It is insoluble in pure alcohol. The crystals of nitre, though the salt is anhydrous, generally contain interstitial water; so that they appear moist when powdered, and lose weight on drying. The taste of nitre is cooling and peculiar, and it is used in medicine in small doses, as a diuretic and sedative: in doses of from half an ounce to an ounce it is poisonous, exciting spasms, vomiting, bloody stools, convulsions, and often proving fatal. In such cases viscid mucilaginous drinks with opium and cordials are the most effective restoratives. This salt consists of

Potassa . . . 1 . . .	48 . . .	47.1 . . .	Wollaston, 46.668

At a temperature of about 600° , nitre fuses without undergoing change of composition, and congeals, on cooling, into a white striated mass. Sometimes it is cast into small balls or cakes, called *sal prunella*, a name said to be derived from the circumstance of its having been occasionally stained of a plum-colour. At a red heat, nitre is slowly decomposed; and if distilled in an earthen retort or gun-barrel, it affords abundance of oxygen gas, one pound yielding about 12,000 cubic inches, of sufficient purity for many common experiments in which that gas is used; it is of course mixed with a portion of nitrogen. In this decomposition the nitre is first converted into *hyponitrite of potassa*, which is deliquescent; and afterwards, according to Berzelius, compounds are formed of potassa with nitric and nitrous oxides.

* Professor Daniell has shown that in the electrolysis of a solution of nitre, the results indicate that an atom of potassium travels to the negative electrode, and an atom of nitrogen and six atoms of oxygen to the positive electrode; hence the electrolytic formula of nitre is $(n+6o)+po$. He calls it an *oxynitron of potassium*. (*Phil. Trans.*, 1839, p. 109, and 1840, p. 223.)

Nitre is rapidly decomposed by charcoal at a red heat; and the results are carbonic oxide and acid, nitrogen, and carbonate of potassa, formerly called *nitrum fixum*, and *white flux*. The old chemists used to perform this detonation in retorts connected with capacious receivers, which were generally blown to pieces; sometimes they succeeded in obtaining a little acidulated water, which they called *chlyssus of nitre*, and attributed to it wonderful medical virtues. These mixtures of nitre and charcoal form the basis of a variety of compositions used for fireworks, the rapidity of the combustion being modified by the relative proportion of the charcoal. When phosphorus is thrown upon nitre, and inflamed, a vivid combustion ensues, and a phosphate of potassa is formed. Sulphur sprinkled upon hot nitre burns, and produces a mixture of sulphate and sulphite of potassa, formerly employed in medicine, under the name of *Glaser's polychrest salt*. The combustion of a mixture of sulphur with a small quantity of nitre has already been described as the source of sulphuric acid (p. 463). When a mixture of two parts of nitre and one of hydrochlorate of ammonia are heated to redness, chloride of potassium, water, chlorine, hydrochloric acid, and a little nitrous acid, are the results, and nitrogen gas is copiously evolved. (SOUBEIRAN, *Journal de Pharmacie*, 1827, p. 321.) Most of the metals, when in filings or powder, detonate and burn when thrown on red-hot nitre; some of the more inflammable metals produce in this way a considerable explosion.

A mixture of three parts of nitre, two of dry carbonate of potassa, and one of sulphur, forms *fulminating powder*. If a little of this compound be heated upon a metallic plate, it blackens, fuses, and explodes with much violence, in consequence of the rapid action of the sulphur upon the nitre, and the sudden evolution of nitrogen in its gaseous form.

The action of sulphuric acid on nitre has been described above (p. 416), and will be again adverted to under *sulphate of potassa*. When nitre and hydrochloric acid are heated together, chlorine and nitrous acid are evolved, and on evaporation to dryness, chloride of potassium remains. Mr. Penny proposes this decomposition as the basis of a method of ascertaining the quantity of nitrate of potassa in crude saltpetre. (*Phil. Trans.*, 1839, p. 13.)

GUNPOWDER consists of a very intimate mixture of nitre, sulphur, and charcoal, the proportions varying, according to the uses made of it, as follow:—

	Common gunpowder.	Shooting powder.	Shooting powder.	Miners' powder.
Saltpetre	75.0	78	76	65
Charcoal	12.5	12	15	15
Sulphur	12.5	10	9	20

The following is a table of the composition of gunpowder of several countries:—

	Nitre.	Charcoal.	Sulphur.
Waltham Abbey mills	75	15	10
France, national establishment	75	12.5	12.5
— for sportsmen	78	12	10
— for mining	65	15	20
United States of America	75	12.5	12.5
Prussia	75	12.5	12.5
Russia	73.78	13.59	12.63

	Nitre.	Charcoal.	Sulphur.
Austria	76	11.5	12.5
Spain	76.47	10.78	12.75
Switzerland (round powder) . . .	76	14	10
Chinese	75	14.4	9.9

The ingredients are *perfectly* mixed, moistened, beaten into a cake, which is afterwards broken up, granulated, dried, and for the finest powder polished by attrition. The violence of the explosion of gunpowder depends upon the sudden production of gaseous matter, and of intense heat, resulting from the action of the combustibles upon the nitre. Carbonic oxide, carbonic acid, nitrogen, and sulphurous acid, are the principal gaseous results; and the solid residue consists of carbonate and sulphate of potassa, sulphuret of potassium, and charcoal. (CRUICKSHANKS, *Nicholson's Journal*, iv. See also the same *Journal*, xiii. 277.)

If we theoretically inquire how the maximum gaseous volume is to be produced from the chemical reaction of the elements of gunpowder, we shall find it to be by the generation of carbonic oxide and sulphurous acid, with the disengagement of nitrogen. This will lead to the following proportions of their constituents. (URE, *Journal Royal Institution*, vol. i. p. 135.)

		Per cent.
1 equivalent of nitre . .	102	75.00
1 " sulphur . .	16	11.77
3 " charcoal . .	18	13.23
